Definition

Pemoline is an older psychostimulant that is now off the market. Pemoline shares features in common with amphetamine and methylphenidate. It was removed from the market due to concern about rare problems with liver failure. Pemoline has not been well studied in children with pervasive developmental disorders.

Definition

Perception includes the selection, organization, and interpretation of external information coming from the senses up to a complete representation of a stimulus. The extraction of elementary features within primary cortical receiving areas in each sensory modality is called low-level perception. It is domain general such that the same mechanisms are involved in processing social and nonsocial information. At a higher level of integration, there is pattern construction in which elementary features (e.g., of visual or auditory stimuli) are grouped into basic configurations. Visual motion perception depends on information integrated at various levels of the processing hierarchy: first-order motion is perceived in primary areas, while second-order motion requires a

network of associative regions. High-level perception involves the matching of constructed configurations with memorized templates as the hierarchy of perceptual processing becomes gradually more domain specific. In turn, domain-specific perception includes face and emotion perception, language perception, and, for dynamic information, perception of biological motion.

Perception typically feeds to and receives information from other major functions in the cognitive architecture, including emotion, language, memory, attention, expectations, and conscious reasoning. Thus, perceptual configurations may be associated with innate or memorized patterns of biological significance, pattern construction is influenced by language categories, and pattern recognition involves an active comparison of perceived and stored configurations. Perception is a dynamic process which modifies (bottom-up) and is modified by (top-down) higher-level cognitive processes.

Historical Background

Kanner's initial writings emphasized autistics' attention to and production of perceptual information (e.g., gazing at moving objects, lining up objects by color) as essential elements of autistic repetitive movements and behaviors. He vividly described extraordinary autistic achievements in memory, construction, and attention to detail. Perception-based behaviors, he noted, were associated with extreme emotions, such as being "ecstatic" while watching spinning objects or displaying panic in response to sounds. In his later writing, Kanner (1965, p. 412) underlined that being "so concerned with the external world that they watch (it) with tense alertness to make sure that their surroundings remain static (...) in full photographic and phonic identity" is inconsistent with the withdrawal into one's own world implied by the label autism.

Early models such as *perceptual inconstancy* (Ornitz 1973) were formed around the apparently paradoxical co-occurrence, within the same modality, of overt hypo- and hyperreactions to perceptual information (e.g., to voices and

vacuum cleaners, respectively). Atypical social and nonsocial representations were linked to subcortical abnormalities distorting perceptual input. However, absence of replicated brainstem event-related potential (ERP) abnormalities coupled with lack of empirical confirmation that perception in autism is unstable led to these models being abandoned in the early 1980s.

Meanwhile, early studies by Hermelin, O'Connor, and Frith in the 1960s and 1970s (Hermelin and O'Connor 1970; Frith and Hermelin 1969) established alternatively the absence of gross abnormalities in low-level processing. Performance in pattern reproduction, recognition, and memory was therefore considered to be unremarkable in autism. These studies were focused on the detection and imposition of a structure on visual or verbal materials, corresponding partly to pattern construction and partly to what would be now called top-down influence on perception. They concluded that autistic cognition was skewed toward meaningless or raw information, while structure imposition and recoding were diminished or absent. However, examples brought to support these positions – hyperlexia, echolalia, and 3-D drawing – implied pattern manipulation and not raw material. A decisive synthesis by Frith and Baron-Cohen (1987) concluded that “low level processes are intact in autistic children” (p. 98) and “what appear to be signs of a lower level dysfunction can be explained more powerfully in terms of a higher level cognitive dysfunction” (p. 87).

Those two conclusions, that autistic perception was unremarkable and that apparent atypicalities resulted from higher level impairment, dominated autism research for two ensuing decades, including by influencing the interpretation of autistic perceptual strengths. When administering visuo-spatial tasks, autistics were found to perform better than predicted by their other abilities and better than groups of intellectually disabled individuals matched on apparent IQ. In testing with Wechsler scales of intelligence, Rutter (1966) reported superior autistic performance in the block design subtest, which is based on visuo-spatial abilities. In 1983, this early accidental finding was extended by Shah and Frith in a

deliberate investigation of autistics' performance on the embedded figure task, which is also based on perception and manipulation of visual patterns. Autistics performed at a level superior to that predicted by their IQ (Shah and Frith 1983).

The weak central coherence (WCC) model, elaborated by Frith (and later, with Happé) starting in the late 1980s, accounted for such autistic peaks in performance by positing a causal deficit: autistics were not displaying atypical perceptual *strengths* but a *failure* to form global or high-level representations. WCC-based interpretations were consistent in direction with the period's cognitive research, which in the 1980s and 1990s remained oriented toward multiple high-level processing deficits, such as deficits in theory of mind, executive functioning, and complex tasks in general. In addition, Minshew's group discouraged diagnostic use of perceptual peaks by emphasizing that they were not found in all autistics. Fine-grained research on autistic perception emerged in the 1990s as a minority current.

The tenets of WCC were questioned in 1993 in the first study extensively investigating visual perception in an autistic adult, according to the concepts and instruments of cognitive neuropsychology at the time (Mottron and Belleville 1993). The local–global hierarchical aspect of visual perception was atypical in the form of greater interference from local to global levels and random access to features of perceptual representation but without deficits in pattern construction. Findings inconsistent with WCC-predicted deficits in auditory and visual pattern construction at the group level, together with discoveries of superior discrimination of low-level visual arrangements (Plaisted et al. 1998) and superior pitch processing (Heaton et al. 1998), then led to the enhanced perceptual functioning (EPF) model. This model originally aimed to relocate autistic perceptual peaks within an overall enhanced activity and performance of the perceptual system, including enhanced pattern construction mechanisms. However, EPF did not initially question Frith's or Minshew's preconception that autistics' overall superior perceptual performance was a secondary consequence of deficits in high-level

processes. This step was accomplished in an update of EPF (Mottron et al. 2006) based on the blossoming of studies on perception in autism after 2000.

The updated EPF model proposed that autism is characterized by enhanced perceptual *performance* in low-level (e.g., pitch processing) and mid-level (e.g., pattern detection) perception, enhanced *autonomy* of perception toward non-perceptual systems (emotional and higher-order architecture), and enhanced *role* of perception in higher cognitive processes (e.g., enhanced role of perception in intelligence and in social tasks). In other words, enhanced perception in autism was therefore proposed as such, rather than as evidence for speculated high-level deficits. Multiple other groups (including M. Behrmann, A. Bertone, P. Heaton, C. Manning, E. Milne, P. Mitchell, E. Pellicano, K. Plaisted, J. Remington, A. Swettenham, J. Wagemans) now investigate the relation between low-level perceptual processing and various aspects of autistic cognition.

Distant from the expanding interest in research, the importance of perception has also evolved within formal autism diagnostic criteria. Autism in DSM-III included indirect reference to perception-guided repetitive behaviors: “Bizarre responses to various aspects of the environment, e.g., resistance to change, peculiar interest in or attachments to animate or inanimate objects.” DSM-III-R referred to “Persistent preoccupation with parts of objects (for example, sniffing or smelling objects, repetitive feeling of texture of materials, spinning wheels of toy cars)” and DSM-IV to “Persistent preoccupation with parts of objects.” Perceptual issues are now more explicitly included in the DSM-5, albeit as “hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment.” Perception-related behaviors are included in ADI-R and ADOS-G diagnostic instruments as atypical positive and negative reactions to sensory information (“unusual sensory interest,” “undue general sensitivity to noise,” and “abnormal, idiosyncratic, negative response to sensory stimuli”) or as repetitive behaviors possibly related to perception, as in “repetitive use of objects, hand and finger mannerisms.”

Current Knowledge

Perception-Related Behaviors

Perception-related behaviors are usually investigated under the overgeneral definitions of “repetitive” or “sensory” behaviors and by means of wide-ranging scales (e.g., Infant Toddler Sensory Profile; Dunn 2002) using a posteriori scoring in natural, nonempirical settings, with imprecise behavior definitions (e.g., scoring a behavior as present or absent). Their reported lack of specificity and poor sensitivity therefore reflect major methodological issues (Rogers and Ozonoff 2005). In a limited number of cases, studies of perception-related behaviors in empirical settings or using strict definitions have provided evidence regarding their specificity to autism and mechanisms involved in these behaviors. This is the case for atypical visual exploratory behaviors and lateral glances, which are linked to periodic motion (Mottron et al. 2007) and nonrandom visual (geometric) or multimodal (audiovisual synchrony) structures (Klin et al. 2009); and for shorter visual fixations to and faster disengagement from face images, which are associated with an absence of a mandatory bias for faces (Chawarska et al. 2010).

Psychophysical Studies of Low-Level Perceptual Processing

The lowest levels of cortical visual processing, located in V1, include perception of first-order luminance-defined information, to which autistics show enhanced sensitivity compared to non-autistics, when detecting orientation of gratings. Six-month-old siblings of autistic spectrum children also demonstrate enhanced sensitivity to luminance-defined stimuli. Whereas autistics appear to discriminate high and low spatial frequencies at the same level behaviorally as non-autistics, EEG and fMRI reveal between-group differences in brain activity, mainly during high spatial frequency processing. Visual stimuli that fall within the mid-frequency range may be processed using the same mechanisms as those devoted to the processing of high spatial frequency information, providing EEG correlates for the autistic “local bias” evident in pattern

analysis. At a higher level of integration, crowding is the deleterious influence of nearby contours on visual discrimination of a target, attributed to lateral inhibitory interaction of neurons encoding visual properties of nearby distracters. Diminished crowding effects, for which there is preliminary evidence in autism, may allow enhanced segregation of a target from close distracters, offering an explanation for superiorities in visual search.

Autistics have demonstrated atypicalities in some low-level but integrative tasks (Bertone et al. 2005), but as of now, findings are insufficiently homogeneous to posit a deficit in integration. Second-order texture-generated perception requires an integration of primary V1 and associative brain regions V2/V3. The threshold for discriminating the orientation of static second-order gratings is elevated in autism. Early local “binding” mechanisms of contour integration have been investigated, in a search for the lowest-level indication of a putative deficit in grouping processes. However, most recent studies using this method have shown typical behavioral performance in autism, although electrophysiological investigations of contour integration reveal processing differences between autistics and nonautistics. Colors are processed in a complex stream (V1, V2, V4, V8), as second-order visual information, and careful studies show diminished discrimination performance at this level in autistics compared to nonautistics. Components of motion perception, which involve areas V1, V2, and V5/MT, have been studied thoroughly, based on initial findings of diminished influence of perceived motion (optical flow) on postural control and higher thresholds for global motion coherence. When motion perception is decomposed according to the neural complexity required to perceive the motion, perception of first-order motion is preserved, but second-order motion is diminished. Motion coherence tasks measure the ratio of dots within a dot set that have to move together in order to produce a perception of movement, and this perception specifically requires the middle temporal (MT) area. Most recent studies report no group differences, but the variability of results for

motion coherence does not permit firm conclusions with respect to its typicality in autism or its influence on overt behaviors. Sporadically reported autistic differences may result from atypical feeding of information from lower levels and may not be motion specific. Overall there are multiple sources of evidence for atypical low-level visual perceptual processing in autism, some being associated with enhanced behavioral performance, but low-level causative roles in superiorities in pattern detection and manipulation remain to be specified.

In the auditory modality, multiple types of tasks involving pitch perception are performed at a superior level by autistics, representing one of the most replicated areas of autistic superior performance. Task types have included discriminating and categorizing pitches, mapping tonal intervals in a visual schema, memorizing tone-picture associations, determining the direction of pitch-interval correspondence, detecting a named pitch within a chord, memorizing isolated tones and sequences of tones, and detecting a deviant pitch in a sequence of complex sounds. Absolute pitch is considerably more frequent in autistic than nonautistic individuals and, frequently but not always, is associated with savant musical ability. Superior pitch processing has been observed in autistics with or without intellectual disability (according to various measures) but is more frequently observed in autistics whose measured intelligence is in the normal range and who have a history of speech delay.

There are currently no behavioral task findings involving nonsocial simple or complex sounds and a matched group that demonstrate a deficit in autistics. The predicted auditory parallel with possibly diminished processing of second-order visual information has not been found. Robustness of superior pitch processing in autism is confirmed by event-related potentials, which also indicate enhanced detection of pitch changes, mostly in the form of shorter mismatch negativity, shorter latency, or enhanced amplitude. Enhanced low-level auditory perception has a firmly established relation with frequent giftedness in music as well as with atypical language processing and behaviorally observed speech delay.

Other modalities – tactile, olfactory, and taste – have not yet been sufficiently studied to allow any conclusive report. Multimodal integration, which was prematurely considered to be dysfunctional, results in behaviorally normal performance by autistics for integration of low-level perceptual stimuli. However, autistics' verbal labeling of audiovisual integrative patterns may demonstrate sporadic, variable atypicalities.

Cognitive Studies on Pattern Detection, Construction, and Manipulation

Autistics display enhanced performance in tasks requiring detection of a pre-identified local target embedded in a larger probe. Visual search tasks typically consist of detecting the presence or absence of an item among a series of distractors sharing one or several features with the target. The superiority of autistics in visual search is well replicated, encompassing shorter visual fixations, superior discrimination of targets, as well as parallel processing of a larger number of distractors than controls (Caron et al. 2006). Embedded Figures Task (EFT) consists of detecting a simple figure hidden within a complex one. Here also autistics demonstrate a well-replicated superior performance, mostly in the form of increased speed. Another type of task, using hierarchical stimuli, also reveals increased detection of local targets and diminished bias for processing global aspects of a pattern in autistics. Hierarchical or Navon stimuli are typically large “global” letters, numbers, or geometric shapes, composed of small “local” elements, such as a big H composed of small Bs. The task consists of detecting, naming, or matching a component situated at either global (e.g., H) or local levels (e.g., B). Autistics can show more accurate local target detection than typical individuals, while global-level stimuli reaction times are more affected, compared to those of typical individuals, by incongruent local stimuli. In the auditory modality, with musical hierarchical stimuli, autistics reliably display a typical global advantage but either a superior detection of local changes or a diminished global to local interference.

Pattern construction and manipulation are also autistic strengths, first quantitatively reported in

Wechsler Block Design. In this task, the participant has to reproduce a red and white geometric design with a set of red, white and bicolor blocks. Autistics usually perform one to three SDs above their level of IQ, and they outperform controls both in accuracy and RT. In autism, a Block Design (BD) peak is associated with the presence of speech delay. The BD peak has two proposed sources, enhanced perception (e.g., autistics with BD peak are also superior in visual memory, visual search and discrimination) and diminished mandatory influence of global aspects of the figure to be reproduced on local parts matching and manipulation. While visual “local bias” as a general autistic perceptual superiority has been challenged by meta-analyses of Navon- and BD-type performance, it still characterizes a large subgroup of autistic people across a variety of task conditions.

Superior performance in mental rotation tasks in autistics also suggests enhanced construction and manipulation of mental images, which in turn may be attributed to an overall superiority in perceptual performance and to a particular strength in *veridical mapping*, the ability to efficiently detect isomorphisms among entities and make correspondence between these isomorphic features. Autistics also display an enhanced perceptual capacity in visual and auditory modalities.

Domain-Specific Perception: Biological Motion, Faces, and Language

Biological motion tasks consist in recognizing typical human or animal activity from point-light displays. Although the verbal labeling of the motion may be less salient or less automatically produced by autistics, a large fraction of studies have found typical perceptual performance at this level. An fMRI study reporting both similarities and differences in task performance suggests in autistics a diminished involvement of the superior temporal sulcus (STS), an associative region considered central for perception of biological motion in nonautistics.

Atypical overt behaviors toward human faces are diagnostically important in autism. Face processing has therefore been the focus of intense research interest in the past 40 years, yet results

are surprisingly tenuous. Following early experiments suggesting a domain-general local bias, and based on perceptual theories of autism, research on face perception in autism has often focused on the processing of holistic versus local properties of face images. Empirical strategies have included comparison of impact of low- versus high-pass filtering on face image processing, inversion effects including the Thatcher illusion, composite face effects, natural versus nonnatural segmentation of face images, and effects of face context on face part recognition. No clear autistic deficit in the processing of holistic aspects of face images has been found; for example, autistics can display typical face inversion effects, even if not under all experimental conditions. In contrast, there are indications of superior use of face parts for further processing of face images, consistent with an amodal and domain-general local orientation. Typical performance may be obtained through an equalization of relative informative values of low and high spatial frequencies (Simmons et al. 2009).

Studies of ERP responses similarly do not overall indicate an autistic deficit in face processing. Differences reported between responses to face and object manipulation are observed in autistics, indicative of diminished specialization or category specificity. In the same direction, a meta-analysis of regions involved in face-processing tasks indicates that despite activity in typical face-processing regions, other regions are active only in autistics. Autistics show, for example, greater activity bilaterally in extrastriate (BA 18, 19) and striate (BA 17) cortex compared to nonautistics when processing face images (Samson et al. 2012).

In sum, it cannot be stated, as was routinely written in the previous decade, that autistics are characterized by a face-processing *deficit* in that their performance in perceptual tasks involving face images has been comparable to that of nonautistics in most of the tasks used. The ability to use specific parts for face recognition cannot accurately be reduced to a simple deficit; instead, autistics are less strategic and more versatile when scanning faces for whatever purpose. Face processing in autistics seems to rely on a large network of occipital and temporal areas

specifically responsive to certain visual categories in nonautistics.

Atypicalities in speech development and behaviors when exposed to vocalizations are key diagnostic features of a large fraction of the autistic spectrum, such that one could expect perceptual processing of speech to be precociously impaired. The most reliable finding on the relation between auditory perception and speech processing is the coexistence of speech delay in infancy and superior pitch processing at an adult age, albeit the latter is not predictive of speech level at an adult age. Behaviorally, discrimination of the physical aspect of speech (pitch contour) may be superior in autistics, whereas nonautistics cannot attend to a physical property of an auditory pattern without being distracted by its linguistic dimension (Jarvinen-Pasley et al. 2008). A perceptual component may be implicated in the reported difficulty in speech recognition in noise or atypicalities in prosody perception. However, it should be interpreted in relation with superior processing of written alphabetical and numerical material, commonly observed in autistic children with a speech delay.

In terms of material-specific cortical specialization, a reduced leftward asymmetry has been reliably observed for speech processing. Discrimination and orientation to spectrally and temporally complex speechlike material results in atypical, generally diminished brain activity for ERP components indicative of attention to sounds. Autistics exhibit diminished activity in nonprimary auditory cortex and increased activity in primary auditory cortex in response to the presentation of temporally, but not of spectrally complex sounds. Greater temporal complexity effects in primary auditory regions sensitive to acoustic features and reduced temporal complexity effects in auditory regions sensitive to more abstract sound features could represent a greater focus toward perceptual aspects of speech sounds in autism.

Relation with Other Elements of the Cognitive Architecture

Perception is a multilevel system that provides information to but also receives information

from multiple other components in the cognitive architecture. Both feedforward and feedback influences involving perception present some atypicalities in autistics. For example, in non-autistics, feedback from pattern formation to low-level perception sometimes produces visual illusions and distortions. In a visual illusion, the judgment on properties of a visuospatial element is altered by its inclusion in a larger visual context. Autistics display less (but still some) susceptibility to some visual illusions when compared to typical individuals. Categorical perception also produces distortions in nonautistics, as feedback influences from learned categories alters the saliency of perceptual properties of a stimulus. Despite similar categorization abilities, autistics' discrimination is less influenced by categorical knowledge.

There are indications that in autism, visual perception plays a superior role in high-level cognitive processes, which are more language-mediated in nonautistics. For example, lateral glances toward faces and prolonged lateral inspections of rotating objects influence the course of directed attention in autistic toddlers. One of the strongest findings in autistic visual perception, robust enough to be valid across tasks, is revealed by a functional imaging meta-analysis of all tasks implicating visually presented material, in which autistics present superior activity across a broad expanse of brain regions involved in visual perception and perceptual expertise. This suggests that perception plays a superior role in complex cognitive operations – encompassing language, problem-solving, reasoning, etc. – with effects on performance that are not necessarily detrimental and are sometimes beneficial (Samson et al. 2012).

Atypicalities in the relation between components of perceptual processing, as well as between perception and other parts of the cognitive architecture, have naturally oriented toward Bayesian and predictive coding re-interpretations of perception autism. While this has produced elegant and concise theoretical constructs, it has not yet enriched our body of empirical results on autistic perception.

Connections and influences between perceptual brain regions and other brain regions have

now been studied through investigations of structural and functional connectivity. Structural studies including the visual cortex reported altered connectivity in the direction of a diminished integrity of white matter fibers in autistics compared to nonautistics. Despite the small number of studies and the variability in the participants' diagnoses and age, these investigations revealed that visual areas are atypically connected mainly to regions in the temporal lobes but also in frontal and parietal lobes as well as thalamus. Task-related functional connectivity studies mainly show results in the same direction, that is, less correlation between the activity of visual areas and other cortical regions in the frontal, parietal, or temporal lobes, during a wide range of tasks.

Conclusion

Atypical autistic perception was one of the key elements of Kanner's seminal description. The early accounts of perception in autism hypothesized either an abnormal and inconsistent distorting of perceptual input or, alternatively, an unremarkable perception, producing a raw, uncoded representation of the world. First accounts of perception-related behaviors concluded that there was a lack of specificity compared to other neurodevelopmental conditions. The role of these behaviors in diagnosis was minimized, as they were merged with other repetitive behaviors in DSM definitions of autism.

Within the last two decades, these views have profoundly changed. There is now a consensus that the autistic visual and auditory systems provide the rest of the brain with qualitatively, and quantitatively, different information than in nonautistics. Superior performances in nonsavant auditory perception have as yet mainly been found through investigations limited to low-level processes. However, wider-ranging studies have revealed that superior performances in visual perception often imply pattern detection and manipulation, indicating that autistic perception does not produce a raw, uncoded representation of the world. In both modalities, peaks in perception can be correlated with speech delay, suggesting a

relation between the two factors. Relations with nonperceptual components of the autistic cognitive architecture are asymmetrical. On the one hand, perception is more autonomous with regard to emotions, expectations, and language-mediated processes. Autistic perception is more veridical and immune to distortions resulting from top-down influences than in typical individuals. On the other hand, superior brain activity in perceptual associative visual areas is evident in a large array of tasks, suggesting that perception plays a superior role in complex, language-loaded, intelligent cognitive operations, without mandatory detrimental effects on performance.

Concerning relations between perception and other areas of atypicality, autistic perception cannot be straightforwardly explained by cognitive models focused on high-level processes: “perceptual alterations are present in ASD, independent of social function” (Behrmann et al. 2006, p. 263). However, non material-specific peculiarities in perception have the potential to explain autistic characteristics in the diagnostic sociocommunicative as well as in the repetitive behaviors and restricted interests domains. This potential remains underexplored, but there is growing recognition of the “great need for further exploration” of fundamental low-level perceptual atypicalities in autism (Belmonte et al. 2004, p. 658).

Future Directions

- The cartography of autistic low-level perceptual processes is far from complete. Still to be sufficiently investigated are the following: in vision, contrast and (to a lesser extent) colors; and in audition, lateral inhibition, inspection time, among others.
- Multiple auditory equivalents of visuospatial peaks have not yet been investigated.
- The aggregation of auditory and visual perceptual peaks in the same individual is yet unknown.
- The biological substrates, at the cellular level, of enhanced discrimination of low-level information (e.g., pitch) are unknown.

- What is the relation between actual or proposed delineations of the autistic phenotype (e.g., having or not a speech delay) and perceptual characteristics?
- What is the relation between “sensory” issues, as mentioned in the DSM 5, and neuroscience accounts of autistic perception?

Perceptual Development

Jennifer Varley Gerdtz

Department of Psychology, University of Washington, CHDD, Seattle, WA, USA

Definition

The perceptual system recreates the surrounding environment in the brain based on information provided from the senses: vision, hearing, smell, taste, and touch. Therefore, perception provides the *experience* of the environment and is a means to act according to what is occurring in the environment (Berk 2000; Goldstein 2002).

The general perceptual process involves a series of steps that originate from the environment and involve the recognition of a stimulus and subsequent action regarding that stimulus (Goldstein 2002). Perception is not a static process but rather is dynamic and continually changing based on successive actions and perceptions. For instance, an infant's advancing motor development allows the infant to better explore and learn about the world around him/her. The improved perception resulting from advancing motor skills in turn brings about more effective motor activity. Therefore, general motor development and the resulting perceptive experience support each other in providing infants with increasingly advanced motor and perceptual systems (Bertenthal and Clifton 1998).

Likewise, perceptual development is a continually changing process that advances rapidly in the first years of life and involves an interaction

between the environment and innate bodily systems. This entry will review the development of human perception in typically developing infants and discuss what is known about perceptual development in autism.

Historical Background

Knowledge of perceptual development has grown significantly over the centuries. The belief of preformationism abounded during medieval times. This meant that infants and children were considered to be just smaller versions of adults, with the same perceptual capabilities (Berk 2000). Later centuries watched the pendulum sway in the other direction, with respect to child development. The writings of the British philosopher John Locke propelled the belief that human infants were born as a “tabula rasa” or “blank slate.” Experience was deemed to be necessary for perception to occur (Thorne and Henley 2001). For example, Locke believed that a blind man given sight would have to learn to recognize objects visually. Newborn infants were believed to be capable of nothing and required adult teaching to be shaped into a functioning child and adult. Similarly, nineteenth-century psychologists believed that young infants were not able to perceive or make sense of the stimulation received from their environment (Goldstein 2002). Infants were believed to be functionally deaf until they experienced stimulation from the environment.

G. Stanley Hall, an influential psychologist in the early twentieth century, was inspired by Charles Darwin’s work in evolution. He put forth the idea that child development is genetically predetermined and unfolds automatically (Berk 2000). James Mark Baldwin was an American psychologist publishing at approximately the same time and believed that both the child’s innate capabilities and the surrounding environment are crucial to development. Baldwin’s line of thinking can be seen in many modern-day views on perceptual and general development in children.

More accurate ways of measuring infant perception have allowed psychologists to discover that babies are able to perceive input from all

five senses at birth and that these abilities advance rapidly in the first months of life. While perceptual development tends to follow a general trend that is partially dictated by biological capabilities, perceptual development is dependent on appropriate experiences with the environment.

Current Knowledge

Perceptual Development in Typical Children

Overview

In typical development, most perceptual capacities develop rapidly during the first year of life. Those abilities that are not present at birth generally surface during an infant’s first month. Perception serves as an infants’ first knowledge of the world gathered through the senses and provides the basis for cognitive development (Berk 2000). Many researchers posit that an infants’ general development shifts from an early emphasis on perception and understanding sensations in the first year of life to a later focus on cognition (e.g., Mandler 1998). Infant perception of the environment is informative and influential in other aspects of development as well (Hatton et al. 1997). For instance, hearing is clearly very important in the development of language. Touch, vision, and hearing provide a means for humans to interact with one another and are therefore fundamental in emotional and social development.

Additionally, infants are able to combine information from various modalities and sensory systems. This intermodal perception appears to be present from birth as demonstrated by studies examining infants’ ability to combine diverse sensory inputs. For instance, one study demonstrated that newborns preferred to look at a pacifier shape that they had previously sucked versus one they had not, indicating that infants can integrate touch and vision from birth (Meltzoff and Borton 1979). Additionally, by 7 months of age, typically developing infants were able to match emotional facial expressions that they saw on a screen to varying vocal expressions in an adult’s voice (Soken and Pick 1992). This finding suggests that older

infants can integrate relatively advanced input received from vision and hearing senses.

The development of perceptual abilities is a dynamic process that depends on the interaction between the environment and biological capabilities. A baby's desire to explore its environment coupled by neural and central nervous system development, capabilities of the body, and environmental support provides the medium in which typical development occurs (Berk 2000; Goldstein 2002).

Certain aspects of stimulation are particularly important to young infants, without which deviations from typical development can occur. For instance, a number of studies have been conducted on orphans from Romania who were raised in institutions with horrific conditions (Rutter and The English and Romanian Adoptees Study Team 1998). Noticeable differences in outcome were observed in infants who were adopted between 0–6 months, 6–12 months, and 12–24 months of age, with those infants living in the conditions longer demonstrating greater impairment (Rutter and The English and Romanian Adoptees Study Team).

White and Held (1966) describe a study examining the timing of reaching in infants living in institutions who were provided with high, moderate, and low levels of stimulation. They reported that institutionalized infants who received a moderate amount of stimulation in the first months of their lives reached for objects 6 weeks earlier than those given low levels of stimulation. Although babies receiving a high amount of stimulation also reached for objects sooner than those babies given low levels of stimulation, these infants tended to cry and fuss more often than the other two groups. The authors interpreted findings to mean they were perhaps overwhelmed by the amount of stimulation provided in their environment and suggested that appropriate levels of stimulation (not over- or understimulation) are important to development and adjustment in human infants (White and Held 1966). Studies such as this and the studies on Romanian adoptees demonstrate that typical development cannot occur without proper environmental support.

Assessment of Infant Perception

Infant perception is difficult to assess because babies cannot clearly express what they are thinking or perceiving. This can be especially difficult in newborns and young infants when researchers need to wait for infants to enter a “quiet alert” phase, obtain permission from new mothers, and adapt to rapid changes in infant attention (Goldstein 2002). Therefore, researchers have altered their research questions and methodologies to answer the more basic question: Can infants tell the difference between stimulus A and stimulus B (Goldstein 2002).

A number of creative methodologies are used to examine perception in infancy. One procedure uses visual attention and is called “preferential looking.” If infants look longer at a particular stimulus versus another, researchers assume that the infant can tell the difference between the two. If they look at the two stimuli for the same amount of time, then experimenters assume that infants cannot tell the difference (Goldstein 2002).

An additional methodology takes advantage of infants' preference for novel versus familiar stimuli. Using a procedure called “habituation,” a stimulus is shown repeatedly to an infant over a number of trials. When the infant's looking time significantly decreases (because the novel stimulus has become familiar), they are considered “habituated.” Once the infant is habituated, a novel stimulus is introduced, and researchers note if the infant's looking time significantly increases with the novel stimulus (“dishabituation”). If it does, researchers assume that the infant can tell the difference between the old and new stimulus. If not, it is assumed that they cannot tell the difference. A variation on this procedure involves following the infant's sucking patterns on a pacifier. After habituation occurs, a novel stimulus is introduced, and researchers track whether or not the sucking pattern changes with the new stimulus. If it does, researchers again assume that infants can differentiate the two stimuli. If not, it is assumed they cannot. This procedure is often used to assess perceptive abilities in response to other sensations (e.g., hearing and smell).

Vision

Vision is the least well-developed sensation at birth. However, visual acuity significantly improves over the course of the first year of life, beginning at approximately 20/400 acuity at birth and advancing to adult visual acuity (20/20) after 1 year (e.g., Courage and Adams 1990). Although newborns can see objects with high contrast at very close distances, they cannot distinguish objects with low contrast and those at a distance. Poor visual abilities at birth are present because the visual cortex is not fully developed and cones in retina (fovea) have poorly developed receptors (Goldstein 2002).

Visual perception contributes substantially to other aspects of development as well. Infants who have limited visual input (i.e., those infants who are blind or have very poor vision) have been found to be delayed in other areas, including cognition, motor, and language (Hatton et al. 1997). Social development in blind infants is also impacted. Infants who are blind do not make eye contact and show limited insight into other non-verbal cues as well. Compared to sighted infants, blind infants less often initiate social interactions and have difficulty interpreting others' reactions and responding appropriately (Preisler 1991). Emotional expressiveness is also limited in this population (Tröster and Brambring 1992). These factors can impact the parent-child relationship in infants with visual impairment, and increased stimulation combining other senses (e.g., sound and touch) is recommended to address the social needs of blind infants. Research in this area provides further evidence that perceptual abilities have a direct association on other aspects of human development.

Faces and Facial Expression

The lack of contrast in human faces makes it difficult for typical newborns and very young infants (i.e., less than a month of age) to differentiate faces and recognize facial expressions. Studies do show that 2–3-day-old infants can recognize their mother's faces as demonstrated by a tendency for infants to look longer at their mother's face (both in person and on videotape)

versus an unknown woman (e.g., Bushnell et al. 1989). However, follow-up studies reported that it seems to be the mother's hairline that the infants recognize rather than the face itself because when scarves covered the women's hairlines, newborns showed no preference for one versus the other (Pascalis et al. 1995). By 3–4 months, typical infants can see facial expressions because their contrast perception has improved and can discriminate happy faces from angry, surprised, and neutral faces (e.g., LaBarbera et al. 1976). Other studies show these skills emerging at 7–10 months of age (Ludemann 1991).

Infants as young as 2 months scan between the eyes and mouth of a human face (Bronson 1991) and track face-like patterns moving across their visual field farther than they will track other objects (Morton and Johnson 1991). While some researchers interpret this to mean that humans have a built-in capacity for perception of faces, others have argued that infants younger than 2 months cannot do so, and therefore, the skill cannot be innate. It is possible that the high level of face-to-face interaction that occurs between infants and caregivers contributes to the refinement of face perception. Whether it be innate versus environmental, infant sensitivity to the human face paves the road for the earliest social relationships (Berk 2000).

Refinement of Visual Abilities

Movement may be the earliest form of visual attention. Infants prefer stimuli that move across their visual field, and movement helps define boundaries of objects, likely allowing very young infants to distinguish two objects (Kellman 1996). Infants have a preference for biological motion representing the visual phenomenon of moving, animate objects. By 4–6 months, infants prefer to look at biological motion versus random dots on a screen (Fox and McDaniel 1982). Color perception develops in the first few months of life, and by 2–3 months of age, infants experience a wide range of colors (Brown 1990).

Depth perception involves the ability to judge the distance of objects from one another and

ourselves. In order for infants to reach for objects, they must have a sense of depth. Since each retina of the eye captures images in two-dimensional images, a translation is necessary to perceive three-dimensional input. Binocular disparity (when retinal images of an object fall on different points of the two retinas) helps in depth perception and develops in typical infants by 3 months (Birch 1993). Visual cues also help to detect depth: pictorial depth cues such as overlap, relative height, and relative size develop by 7 months (Yonas et al. 1986).

Depth perception has also been assessed using a paradigm called a “visual cliff,” in which a “deep” side of a box is covered with glass. Researchers found that crawling infants do not cross from the “shallow” to the “deep” side, suggesting that they can perceive apparent differences in depth (Gibson and Walk 1960). Those with more experience crawling were less likely to cross the cliff (Bertenthal et al. 1984), suggesting again that experience with the environment is important in developing perceptual abilities. Independent motor movement (such as crawling) is crucial in developing problem-solving skills and promotes a new level of brain organization (Bell and Fox 1996). Specifically, it encourages synchrony across the regions of the cerebral cortex and strengthens neural connections involving vision, motor planning, and understanding of space.

Hearing

By approximately 6 months of age, an infant’s ability to hear is similar to that of an adult. Prior to 6 months, infants can hear high- but not overly low-intensity sounds (Olsho et al. 1988). In terms of sound location, by 8 weeks, infants can locate two objects that are within 27°. By 18 months, they locate objects within 5°, which is close to adult levels of 1° difference detection (Morrongiello 1988).

Preference for Speech

Typical infants prefer complex sounds, such as the human voice, to other pure tones (Bench et al. 1976). Specifically, babies show a preference for human speech that is high pitched, expressive, and rises in tone at the end of words and phrases (Aslin et al. 1998). This type of speech is often

termed “motherese.” Infants also seem to prefer the sound of their mother’s voice to that of a stranger. After a learning trial, 2-day-old infants changed their sucking patterns on a pacifier to hear their mother’s voice over a stranger’s voice (Spence and Decasper 1987). Infants as young as 1 month can identify differences between certain speech sounds (such as “ba” vs. “pa,” Eimas et al. 1971). Infants are also able to classify vowels regardless of whether the speaker is a male or a female, which demonstrates “equivalence classification” (Kuhl 1983). This is important because when babies begin to make their own sounds, their voices will be much higher pitched than adults, yet they still need to know that their sound production is equivalent. Infants are also able to obtain information about emotions through the human voice. They are able to distinguish happy versus sad-sounding voices by 3 months (Walker-Andrews and Grolnick 1983).

Speech perception is also influenced by experience. At birth, infants are able to distinguish all speech sounds within all languages. Over the course of the first year of life, they begin to specialize in their native language and are then only able to distinguish sounds that are in their native language. For instance, young Japanese infants can distinguish the English/r/ versus/l/ but cannot at 1 year old (e.g., Kuhl et al. 1992).

Smell and Taste

Smell and taste are the most highly developed senses at birth. Young infants show a disgusted facial expression to the smell of rotten eggs and shrimp and a happy expression to the smell of bananas and vanilla (Steiner 1979). Nursing infants can distinguish the smell of their mother’s breast from that of another nursing mother. In one study, infants spent more time turning toward their own mother’s breast pads than another woman’s pad (Marlier et al. 1998). Newborn babies can discriminate sweet-, sour-, and bitter-tasting stimuli (Steiner 1979). The perception of salty tastes comes a few months later, perhaps in preparation for infants to eat solid foods (Beauchamp et al. 1994). These findings suggest that infants can perceive differences in smell and taste at very early ages.

Touch

Sensitivity to touch is also well developed at birth. Newborns respond to touch, especially around the mouth, palms, and soles of feet. They also react to changes in temperature as well as pain. Sensitivity to touch makes babies more responsive to their environment. In one study, the soft touch of an experimenter caused infants to smile and become more attentive to the adults' face (Stack and Muir 1992). Once infants are able to grasp and reach for objects themselves, touch becomes the primary means through which they explore the world. For instance, they often mouth new objects, then remove the object, then look carefully at it, and then return it to their mouth. Mouthing declines as infants are able to do more elaborate touching with hands by, for example, turning it over, poking it, and feeling the surface while looking intently (Ruff et al. 1992). The famous developmental psychologist Jean Piaget considered touch to be crucial for early cognitive development.

Perceptual Development in Autism Spectrum Disorder

Overview

As discussed above, typical infants have a seemingly innate preference for human interaction and a perceptual system that is prepared to remember and discriminate human faces and voice from a very early age. However, perception of human faces and voice in young children with autism spectrum disorder (ASD) appears to be different. As such, the majority of studies of perceptual development in ASD have involved visual processing, in particular processing of human faces. Preference and processing of particular sounds has also been well studied in ASD. Touch, smell, and taste are less frequently examined in ASD and will not be reviewed in this entry. However, in general, children with ASD often demonstrate sensory sensitivities in these areas and are frequently sensitive to particular textures, tastes, and smells. At times, children react negatively to certain tastes, textures, and smells, while other children are interested in these sensations and actively seek them out. Therefore, perceptual development of these senses may be different in ASD but has been not extensively studied.

Visual Processing

Many studies of visual perception in ASD have focused on face processing and the derivation of organized wholes from perceptual parts.

Local Versus Global Processing

Local processing involves the tendency to focus on parts of a stimulus instead of an organized whole, while global or holistic processing involves perception of the overall stimulus rather than its parts. Weak central coherence is a related concept and involves a difficulty in integrating components to create an overall picture due to an overfocus on parts rather than whole. Children with ASD tend to exhibit weak central coherence and perform well on tasks that capitalize on a local versus a global focus, such as the block design subtest of the Wechsler Intelligence Scale for Children (e.g., Happe 1999). Additionally, they are successful at identifying hidden figures within larger drawings (e.g., Joliffe and Baron-Cohen 1997). However, a number of studies have reported intact global processing in individuals with ASD (e.g., Ozonoff et al. 1994).

Faces

As mentioned, the perception of faces and memory for faces is impacted in ASD (e.g., Klin et al. 1999). Perception of facial affect also seems to be impaired in ASD (Hobson et al. 1988) as well as the perception of direction of eye gaze (Joliffe and Baron-Cohen 1997).

Different brain responses to familiar versus unfamiliar faces and various emotional expressions are noted in 6–7-month-old infants (Nelson and De Haan 1996). In typical individuals, the right fusiform gyrus is more activated during faces than nonfaces stimuli (e.g., Haxby et al. 1994). However, both behavioral and neuroimaging studies indicate that individuals with ASD demonstrate face-processing impairments (e.g., Klin et al. 1999).

Infants at risk for developing ASD due to the presence of an older sibling with the disorder fail to show different brain responses to faces versus objects compared to infants who are not at risk for ASD (McCleery et al. 2009). Young children with ASD again do not show different brain responses to familiar versus unfamiliar faces (Dawson et al.

2002) or faces versus objects (Webb et al. 2006). Additionally, inconsistent patterns of fusiform gyrus activation have been reported with some researchers reporting that areas of the brain involved in processing objects show increased activation during perception of face stimuli (e.g., Schultz et al. 2000). This difference may continue into later adolescence and adulthood (McPartland et al. 2004). The trait is likely familial as parents of children with ASD also show an atypical brain response to faces (Dawson et al. 2005). These face-processing challenges all occur in spite of a normal visual system and retina in ASD. It is important to note that a number of studies have failed to report face-processing differences in ASD (e.g., Webb et al. 2010).

A tendency for configural/local processing and unusual face perception may be related in ASD. Individuals with ASD tend to process faces in a feature-based fashion rather than a holistic approach (Hobson et al. 1988). For instance, when looking at faces, individuals with ASD attend to different elements of the face, such as the lower mouth, compared to individuals without autism (Joseph and Tanaka 2003). Merin et al. (2007) found that infants at risk for ASD spent more time looking at their mother's mouth versus her eyes compared to a low-risk infant group. Additionally, inverting a face does not impact face processing as much in ASD as it does in typical individuals (e.g., McPartland et al. 2004). This lack of difference between processing upright versus inverted faces provides evidence that individuals with ASD may process the face in parts rather than whole. Behrmann and colleagues (2006) reported that the speed in discriminating novel from familiar faces was related to the ability to identify local versus global elements in stimuli, suggesting that the bias for local processing might negatively impact the ability to process faces.

Visual Attention and Disengagement in Infancy

Prospective studies have followed infants at heightened risk for ASD due to having an older sibling with ASD. These studies have documented difficulty disengaging visual attention and increased attention to nonsocial stimuli in a subgroup of high-risk infants compared to control infants (e.g., Bryson et al. 2007;

Zwaigenbaum et al. 2005). In fact, the smoothness of visual tracking at 12 months (but not 6 months) successfully differentiated infants who eventually developed ASD from those who did not (Zwaigenbaum et al. 2005). Infants who would later develop ASD took longer to disengage from an active stimulus to view another stimulus between the ages of 6 and 12 months. Bryson et al. (2007) indicated that high-risk infants at 6 months demonstrated an unusual visual interest and reactivity to objects and lacked smooth visual tracking. High-risk infants in another study spent more time looking at a toy than their caregivers during free play (Bhat et al. 2010). Overall, these studies suggest that ASD-related difficulties with visual disengagement and/or with nonsocial interest in the environment are present in infancy.

Hearing

Delays and impairments in both verbal and non-verbal (e.g., ► [Gestures](#)) communication are often present in ASD and emerge at approximately 12 months of age. As such, perception of speech has been studied in young children with ASD to better understand how infants and toddlers with ASD process and perceive speech.

As discussed, typical infants prefer "motherese" to other types of sounds and speech tones. The use of motherese is influential in other aspects of development, including babies' attention to speech and general language development. Because of this, the responses of young children and infants at risk for ASD to motherese have been examined. Nadig and colleagues (2007) reported that 6-month-old infants at risk for ASD were more likely to show a preference for adult-directed speech over motherese compared to low-risk infants. Furthermore, those infants who preferred adult-directed speech had lower language scores (Nadig et al.). Preschoolers and older children with ASD continue to demonstrate atypical responses to motherese (e.g., Kuhl et al. 2005). Children with ASD preferred listening to mechanical-sounding auditory signals ("sine-wave analogs" that are acoustically matched to speech) over motherese (Kuhl et al. 2005). This preference predicted lower language ability, more severe ASD symptoms, and abnormal brain response to speech sounds.

Social Motivation Theory

Some autism experts believe that perceptual abnormalities such as abnormal face and speech perception are not primary to ASD but are secondary to a fundamental impairment in social motivation (likely due to genetic risk factors). Called the “social motivation hypothesis,” this theory posits that a primary deficit in social motivation causes infants with ASD to fail to attend to and tag relevant stimuli within a social context (e.g., Dawson et al. 2002).

According to this theory, infants at risk for ASD spend less time attending to and truly engaging with people. They may instead be overly focused on objects (Zwaigenbaum et al. 2005). The resulting decreased social engagement discourages the development of a specialization in the processing of the human face and speech. Because experience drives cortical specialization (Nelson 2001), reduced attention to people, including their faces, gestures, and speech, also results in a failure of specialization and less efficient function of brain regions that mediate social cognition (McPartland et al. 2004).

The abnormal perception of interactive stimuli such as face and speech perception is not attributable to a lack of exposure to people. Parents of infants with ASD interact with their infant just as parents of typically developing infants do. Therefore, despite faces and speech being directed at them, ASD infants may not be attending and learning from that context because it may not be interpreted as relevant to them. Social interaction is crucial for many aspects of development. For instance, Kuhl, Tsao, and Liu (2003) indicate that mere exposure to speech in infancy is not enough to learn a language. For language acquisition to develop normally, it must be experienced within a socially interactive environment. Early intervention administered when the brain is still plastic can help guide brain and behavioral development back toward a normal trajectory (Dawson et al. 2010).

Future Directions

Perceptual development is well understood in typically developing infants. While abnormalities in

perception have been documented in older children with ASD, they only recently have been examined in infants at risk for ASD due to the presence of an older sibling with the diagnosis in the family. Prospective studies examining this population from very early in life have provided insight into the development of the disorder in infancy. Additionally, they provide an understanding of how perceptual abnormalities in ASD develop. The few studies examining perceptual development in ASD in infancy have suggested that high-risk infants indeed show different perceptive abilities compared to control infants. Specifically, high-risk infants have difficulty shifting visual attention and show unusual face processing. Expanding these studies to examine the perception of other sensations in ASD, such as hearing and touch, as well as following high-risk infants into preschool and older childhood will broaden understanding of perceptual development in ASD.

Perceptual Organization Index (POI)

Sara D. Rosenblum-Fishman and Danielle Forbes
Psychology, University of Massachusetts Boston,
Boston, MA, USA

Synonyms

POI

Definition

The *Perceptual Organization Index* is part of the Performance Scale of the Wechsler cognitive assessment measures, the Wechsler Intelligence Scale for Children, 3rd edition (WISC-III, 1991), and the Wechsler Adult Intelligent Scale, 3rd edition (WAIS-III, 1997). The POI measures visual-spatial organization and visual-motor skills within a time limit. For the WISC-III, the subtests *Picture Completion*, *Picture Concepts*, *Block Design*, and *Object Assembly* load onto the POI. For the WAIS-III, the subtests *Picture Completion*, *Block Design*, and *Matrix Reasoning* load onto the POI.

The WISC-III and WAIS-III are older versions of the Wechsler cognitive assessment measures, and have since been replaced by the WISC-IV (2003) and WAIS-IV (2008). For both the WISC-IV and the WAIS-IV, the Perceptual Organization Index has been renamed the Perceptual Reasoning Index (PRI). The PRI measures fluid reasoning (use of sequential, inductive, and deductive reasoning) and visual processing (the ability to synthesize and process visual stimuli). Unlike the POI, scores on the PRI are less influenced by speed and the ability to work quickly.

Research has shown that performance on the Block Design task, which loads onto the POI for both the WISC-III and the WAIS-III, is often an area of strength for children with ASD.

Perfectionism

Marilyn Van Dyke¹ and Jeffrey J. Wood²

¹Psychological Studies, UCLA's Graduate School of Education and Information Systems, University of California, Los Angeles, Los Angeles, CA, USA

Synonyms

[Compulsiveness](#); [Exactingness](#); [Preciseness](#)

Definition

Perfectionism refers to the setting of unrealistically high standards accompanied by negative self-evaluations when those standards are not met. When these unrealistic goals are not attained, people with perfectionism characteristics engage

in overly negative self-evaluations, anticipation of catastrophic future consequences, and experience difficult emotions. Perfectionism is linked with psychological disorders including anxiety and depression. Perfectionism may occur in individuals with autism spectrum disorder with some frequency. Perfectionistic tendencies may occur due to cognitive inflexibility that is associated with executive dysfunction of the frontal lobe. Difficulty with shifting attention has been found in this population, with an individual repeatedly performing a task or attempting to solve a problem in the same way over and over. Repetitive behaviors of this type may increase when the person with ASD is under stress or is anxious about something, similar to the type of anxiety that occurs in obsessive-compulsive disorder (Spiker et al. 2012).

In the typically developing population, perfectionism has been linked to social anxiety, depression, and obsessive-compulsive disorder. Perfectionism research in the typically developing population has been conducted using multi-dimensional models (Frost et al. 1990; Hewitt and Flett 1991). Frost et al. (1990) proposed that perfectionism is theoretically comprised of four dimensions: (a) excessive concern with mistakes, (b) a self-doubt about one's abilities, (c) overemphasis on parental expectations and evaluations, and (d) an excessive preference for precision, order, and organization. The maladaptive self-evaluative dimensions of perfectionism have been found to be significantly correlated with anxiety disorders in the typically developing population, specifically social anxiety (social phobia), trait anxiety, and worry (Kawamura et al. 2011). When depression was controlled for, the maladaptive self-evaluative component of perfectionism was not associated with OCD, only with social phobia.

Within the ASD population, it has been found that anxiety disorders occur with great frequency. Recently, there has been research investigating the cognitions and attributions of people with ASD who have anxiety and depression (Greenaway and Howlin 2010). Results indicated that children and

youth with ASD exhibited more dysfunctional attitudes and perfectionism than normal controls. The dysfunctional attitudes were significantly associated with obsessive-compulsive symptoms, and cognitive inflexibility along with social impairments was implicated.

Dentistry, Rochester, NY, USA

Synonyms

[Intraventricular hemorrhage](#)

Definition

Periventricular hemorrhage or intraventricular hemorrhage (PVH-IVH) is a common complication

seen in preterm infants. PVH-IVH occurs in this population because of the metabolically active germinal matrix in preterm infants (before 32 weeks of gestation). This germinal matrix is supplied by a highly vascular and fragile capillary network that is vulnerable to flow and pressure changes. Bleeding in this region may damage the nearby white matter tracts leading to later motor disability and other cognitive deficits.

Periventricular Leukomalacia

Jennifer M. Kwon
Department of Neurology and Pediatrics (SMD),
University of Rochester, School of Medicine and
Dentistry, Rochester, NY, USA

Synonyms

[PVL](#)

Definition

Periventricular leukomalacia (PVL) is the most common ischemic brain injury in premature infants and occurs in the white matter adjacent to the lateral ventricles, just distal to the regions supplied by the deep branches of the middle cerebral arteries. PVL is diagnosed by the typical findings of echodensities on cerebral ultrasound or signal abnormalities of MRI. PVL is an important finding because of the high association with later development of nonprogressive developmental impairments such as cerebral palsy.

Perseveration

John T. Daniai

Psychological Studies in Education, University of California, Los Angeles, Los Angeles, CA, USA

Definition

Perseveration refers to the tendency for behaviors or thoughts to persist independent of social consequences or feedback from the environment. This includes inappropriate maintenance of a current category, repetition of a previous response to a new stimulus, or continued and uninterrupted repetition of a behavior. Perseveration is a deficit in executive functioning and manifests through an inability to shift from one cognitive strategy to another.

Personal Perspectives on Autism

Kabie Brook

Autism Rights Group Highland (ARGH),
Inverness, Scotland, UK

Definition

Definitions of self-advocacy vary; it has been described as follows:

An individual's ability to effectively communicate, convey, negotiate or assert his or her own interests, desires, needs and rights. It involves making informed decisions and taking responsibility for those decisions. (Van Reusen et al. 1994 as cited in West et al. 1999)

Also, as a civil rights movement (Williams and Shoultz 1982 as cited in Goodley, D. and Ramcharan, P. 2005).

However, it is currently defined and it is most often referred to by what could be termed as outsiders – those who aim to define and enhance the concept of self-advocacy but who do not consider themselves to be engaged in self-advocacy; definitions are laden with assumptions and values framed within a normalization agenda. Self-advocacy is seen as something that disabled people may engage in to improve their lot and something that may increase their chances of a more normal or self-directed life. Nondisabled individuals do not generally see self-advocacy as a process that they themselves would be engaged in, but they will debate its meanings.

What of Autistic People's Organisations (organisations run and controlled by Autistic people), those who promote self-advocacy from the inside out as it were? It appears that on the whole, the official line is very much in synch with the aforementioned definition. Looking at www.autreat.com, the website of Autism Network International (ANI), they state that “the best advocates for autistic people are autistic people themselves” but also that some autistic people “are too young, or because they do not have adequate communication skills, are not able to advocate

for themselves.” This, to me, highlights the limited definition of self-advocacy that implies or explicitly states that a level of ability as judged by others is inherently needed to engage in self-advocacy activities. This idea is in line with the thinking that claims that self-advocacy is an acquired skill, something that must be taught in a formal way.

I would like to reconsider these definitions of self-advocacy, to include what may be termed more fundamental or more natural forms of expression of needs, wants, and desires. Is the person who finds their environment unpleasant or even intolerable not also engaging in self-advocacy when they stands and moves to leave a room? How about the person who refuses to board a bus to school but cannot explain that the reason behind this is because of bullying or other abusive experiences that they will encounter on the journey or at their destination? I believe that self-advocacy has become narrowed to such an extent that we are moving it into an elite form of expression; we have allowed nondisabled and more specifically here nonautistic people to define what can and what cannot be termed as self-advocacy. A narrowing to rely on thought through intent, high levels of reasoning, and sophisticated communication with high levels of understanding (as judged by outsiders) leaves those within our autistic communities who are not able to reach these standards languishing.

History

The history of self-advocacy as a named concept can be traced back to the 1960s. At that time, a Swedish activist Dr Bengt Nirje helped disabled people to organize a group which was composed of college students and the disabled people themselves who were expected to make their own plans for activities and were encouraged to make their own decisions, even if mistakes were made. Dr Bengt Nirje described this as “akin to any decent revolt” (Nirje, B. 1969 as cited in *Parallels of Time a History of Developmental Disabilities*).

In the 1970s, the first self-advocacy conferences were held, but still the majority voice was

that of nondisabled people. In 1974 though, the then new organization People First held its first conference with nearly 600 self-advocates in attendance, in Oregon, USA.

At this time, those predominantly engaged in formally recognized self-advocacy were those persons labeled as having learning difficulties, people who had been inspired by the civil rights movement and recognized that disabled people were being left behind.

The inclusion of autistic people in the self-advocacy movement at this time was not overt, but there's no doubt that they were there. Autistic self-advocacy organizations as distinct from the wider self-advocacy movement can be traced back to the early 1990s. Autism Network International (ANI), an advocacy organization run by and for autistic people, was formed in 1992 by Jim Sinclair, Kathy Lissner, and Donna Williams. ANI describes itself as “an autistic run self help and advocacy organisation for autistic people” (autreat.com). ANI went on, in 1996, to present the first Autreat, (www.autreat.com), an annual retreat style conference run by and for autistic people.

Autreat and ANI have become the inspiration for other events, such as Autscope (www.autscope.org), a UK-based annual conference also run by and for autistic people.

Events such as Autreat and Autscope and organizations such as ANI have, over the years, inspired many autistic individuals to speak out, either as individuals or by collaborating and joining together to form a larger more powerful group voice.

ARGH, the organization that I belong to and of which I was a cofounder (www.arghighland.co.uk), was formed when a small group of autistic people came together in 2005 to try to change things for ourselves and other autistic people. Principally a lobbying and campaigning group, we see ourselves as an autistic people's organization engaged in collective advocacy, while at the same time calling for more recognition of self-advocacy.

One of the most well-known autistic self-advocacy organizations is the Autistic Self-Advocacy Network (ASAN) (www.autisticadvocacy.org), founded in 2006. ASAN

has chapters across the USA and more recently in Australia. Ari Ne'eman, the president of ASAN, says, “The object of autism advocacy should not be a world without autistic people – it should be a world in which autistic people can enjoy the same rights, opportunities and quality of life as any of our neurotypical peers” (Ne'eman 2010).

Online organization through message boards and lists has been around almost since the Internet began; in 1994, the ANI listserv started, and in 1996, Martijn Dekker set up Independent Living or InLv for short, an online support group for autistic people.

Communication with each other, sharing experiences, and supporting each other, all of these things contribute to the environment that allows self-advocacy to flourish, at all levels.

Current Knowledge

Even though self-advocacy by individuals and the formation of organizations promoting self-advocacy have been established for some time, the idea of autistic people speaking for themselves is still seen as a novelty by many. One prominent autistic activist says, “Self advocacy is fundamentally about true equality, respect and power, and about recognising and changing the current imbalances in all of those things. Real self advocacy will always upset the status quo in some way” (Baggs 2005).

The dominance of nonautistic voices in conversations about us has remained. Nonautistic advocates speak for us, often without engaging with those they claim to represent to gain a mandate before taking their place at the table to speak for us. Self-advocacy is in itself a contradictory concept in that it only exists as a necessity because of societal expectations, discrimination, and prejudice. Nondisabled people do not engage in self-advocacy when they make choices and speak up for their rights; they are just living their lives.

Autistic people, just as other disabled people and people from other minority groups, are disempowered by societal norms that lead us to engage in what has been labeled as self-advocacy.

This label can be used to replace the more empowering and perhaps more threatening (to those around us) descriptions of what we are actually doing. It raises the question: has our fight for equality been manipulated in meaning to suit an ablest agenda? Self-advocacy is promoted as a way to empower people, but sometimes it feels as though the label is more about presenting requests for equality and rights as a more manageable and acceptable concept to nondisabled people. In this way, a power imbalance can be maintained; norms of society allow us to speak within siloed concepts of “specialness,” with special language describing what others take for granted as usual everyday occurrences or actions.

Mark Neary explores the language of the social care system that can make people’s lives, in this case his son, seem less normal in “ten jargon phrases used for my autistic son,” one example he gives:

If I shout and swear, I’m angry about something. If Steven shouts and swears, it is challenging behaviour and new behaviour management plans need to be drawn up. (Neary 2013)

Neary’s ideas neatly sum up the division between action and perception of action from an outsider’s perspective – nondisabled people. Autistic people are exposed to societal norms that many of us find uncomfortable or alien to us from birth. Many of us receive early intervention – this being seen as essential for young autistic people. Although the term interventions is very broad, and they cannot all be judged to be alike, the pressure to conform, to be indistinguishable, can lead us to a lack of sense of self. Many interventions such as ABA are based upon modifying outward behavior by adherence to the therapist’s instructions; in some cases, this will go as far as how and where a child holds their hands and focuses on an insistence that the nonautistic way is the only way to communicate.

It is difficult to see how these approaches are teaching our young people about selfhood, autonomy, and the value of learning when to say “no.” There appears to be little regard to personhood as an autistic individual, and no examination of what happens to self-expression if autistic expression is

stifled. As Simon Baron-Cohen says, “the need to respect how a person thinks and feels, respecting their real nature, rather than simply focussing on whether they can be trained to change their surface behaviour is essential.”

Future Directions

It is surely our duty as caregivers or community members to ask the following question of all those we entrust to guide our autistic loved ones: how are they being safeguarded to ensure that their personhood and future are protected?

Many parents have been allies to autistic organizations from their inception; this is a concern not only for autistic people but for many who recognize the need for their children (of all ages) to be able to speak up and make themselves heard in any way that they can. For some of us as we age, home living choices, such as what we eat, where we sit, and who we communicate with and how, do grow into political action. Whether the self-advocacy label applies to activism and campaigning (for ourselves or others as self-advocacy is not just about us as individuals) or is about our everyday lives, it is as equally important and valid.

Schools, parents, and other caregivers have a pivotal role to play. It is quite natural for very young children to engage in what may be termed as self-advocacy for us: shouting “no,” turning away from food offered on a spoon, for example. This is quite usual and expected behavior, but after a diagnosis of autism and as we grow, particularly for those of us with limited or non-mainstream forms of communication, our actions can start to be labeled challenging behavior. Our attempts to be heard, to make our needs known, to signal danger, or fear, can be misinterpreted and punished because of our struggle to communicate and to be understood by people who are not experienced in our methods of communication. It is often accepted that self-advocacy is all about the person advocating, that they need to be skilled, and that the onus is upon them to make themselves understood. In fact, this is like any

other form of communication, the receiver has to be in tune with what is being communicated, they must understand and be sensitive, and they must anticipate that a person will be making self-advocacy attempts, understanding the individual's communication style, and adapting to active listening is essential to promote that persons well-being.

Misunderstandings when self-advocacy communication is ignored or mistaken for challenging behavior and the consequences: punishments and being ignored (sometimes quite unintentionally) can start at a very early age. It is easy for people to lose the tools needed for self-advocacy; internalized oppression can become a barrier to effective self-advocacy and mental wellness. If this can be recognized and the need to promote healthy choice making and boundaries that are no more restrictive than those placed upon our nonautistic peers, then we can more effectively sow the seeds for self-advocacy at all levels. By promoting early skills across all learning environments and within the home, we can engineer a situation that guards against loss of self-advocacy skills and ensures that self-determination is more easily fostered throughout the life span. Current self-advocacy training often takes place during transition to adulthood rather than being a lifelong learning experience. All children and young people, not just adults and not just disabled people, would benefit from this approach.

Approaches that encourage autistic people to explore their way of being without expectation of nonautistic behavior and the promotion of autistic voices at all levels: from the playground to the workplace, the boardroom, in government, and always in decisions that affect us or our community are overdue. We need to stop promoting self-advocacy as a novelty, an elite concept for the few, and to recognize that it is for everyone.

In modern society, with the closure of long-stay hospitals, the increasing public awareness of autistic people (and disabled people in general) in our communities and as equals, there should be no need to still separate the right to be heard under a label – self-advocacy. However, in reality, we

have to remember that autistic rights and the fight for equality are still in its infancy, and many of us are still not being heard. The concept of self-advocacy is essential, and the label does have its place to act as a reminder to others to listen; it is very much of its time, but while it is still necessary to give special labels to equal rights, we must reflect upon how much progress we are truly making toward equality from the autistic community and the wider disability community points of view.

[Personality structure in autism spectrum disorders](#)

Short Description or Definition

Personality disorders in autism refer to comorbidity (co-occurring psychiatric disorders). In medicine, comorbidity is relatively straightforward because it mostly concerns well-defined disease entities with known causes (e.g., a fractured leg co-occurring with diabetes). In psychiatry, however, disorders are defined as clusters of signs and symptoms (syndromes), with complicated and uncertain causal pathways. As a consequence, psychiatric disorders show a considerable overlap. This makes it difficult to decide whether symptoms have to be ascribed to either disorder A or disorder B (differential diagnostics) or to both A and B (comorbidity). This issue is important for achieving diagnostic clarity and for managing treatment.

This chapter deals with the dilemma posed when signs and symptoms point to a personality disorders (PD) as well as to an autism spectrum disorder (ASD).

Categorization

Autism Spectrum Disorders (ASD)

In the previous version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), pervasive developmental disorders were subtyped by the Autistic Disorder (AD), Asperger's Syndrome (AS), and the Pervasive Developmental Disorder Not Otherwise Specified

(PDD-NOS). In the new DSM version (DSM-5), these subcategories have been replaced by a single category: Autism Spectrum Disorder.

For the purpose of this chapter, it is important to note that whereas DSM-IV required an onset of symptoms before the age 3 years for the autistic disorder, in DSM-5 this restriction is less strict. Symptoms must be present in early childhood but may not become fully manifest until social demands exceed limited capacities, mostly in adolescence. ASD is diagnosed when there are persistent deficits in social communication and social interaction across contexts and restricted, repetitive patterns of behavior, interests, or activities.

Personality Disorders (PD)

In DSM-IV and DSM 5, 10 categorically defined personality disorders are characterized by enduring and pervasive patterns of inner experiences and behavior (manifested in the areas cognition, affectivity, interpersonal functioning and impulse control); the onset of the patterns can be traced back to adolescence or early adulthood (American Psychiatric Association [APA] 2000). The categorical nature of personality disorders in DSM-IV poses clinicians with classification problems when symptoms are subtle or can also be explained (but not necessarily better) by other disorders or comorbid conditions.

Personality Disorder and/or Autism Spectrum Disorder

The relationship between personality disorders and symptom disorders is complex. Different models have been postulated to describe the shared etiological and pathophysiological factors, such as the predisposition/vulnerability model and the complication/scar model. A promising approach is the model which describes the development and co-occurrence of syndrome and personality disorders as psychobiological in scope (Dolan-Sewell et al. 2001). The Cloninger model (see further below) is an example of this conceptualization. The relationship between PDs and ASD is even more complicated because of the developmental nature of both disorders. While the onset of PDs is theoretically in early adulthood, the first manifestation of behavioral

maladaptive patterns occurs in many instances much earlier on in life. In the diagnostic process of distinguishing PD from ASD, untangling the pathways of symptoms along the lifespan, especially in retrospect, can be a daunting task.

Comorbidity is defined by the presence of two or more disorders present at the same time (Angold et al. 1999; Goldsmith 1999). DSM-IV, however, dictates that if a consistent pattern of experiences or behavior can be better ascribed to the expression or consequence of another psychiatric disorder (e.g., ASD), a PD cannot be diagnosed.

A practical answer to the comorbidity question is that if the clinical presentation of ASD is dominated by major symptoms that would be left underreported if only ASD were classified, it is possible to speak of comorbidity without violating the classification rules. So by classifying a comorbid personality disorder, the clinician draws attention to the complexity of the presentation requiring more than the usual ASD treatment.

However, for clinical purposes, it can be worthwhile to assess personality pathology and traits regardless of whether or not a personality disorder is classified. This is much in line with the proposed DSM-5 methodology.

Epidemiology

There is no reliable data on the prevalence of personality disorders in autism. This is partly due to the earlier mentioned classification rules discouraging diagnosing both at the same time. Like in ASD, assessment of PDs with the “golden standard” (semistructured interviews) is time consuming.

Studies that examined personality profiles in adults with ASD with the Temperament and Character Inventory (Cloninger et al. 1993) show that ASD is characterized by high harm avoidance compared with the norm population, pointing to worrying and pessimistic individuals who are tense in unfamiliar situations or with strangers. In addition, patients with ASD had low scores for reward dependence, indicating little sentimentality and social attachment, and little dependence

on approval of others (Anckarsäter et al. 2006; Sizoo et al. 2009; Söderstrom et al. 2002). The clinical significance of the temperament and character patterns found in patients with ASD is that these profiles sketch in a broad outline the nature and problematic quality of interpersonal relationships between them and others. Other studies showed similar patterns using other instruments like the Autism Spectrum Quotient and the Neuroticism Extraversion Openness Personality Inventory Revised (NEO-PI-R) (Austin 2005; Wakabayashi et al. 2006; Strunz et al. 2015).

Murphy et al. found that particular personality traits may also aggregate in the family members of autistic individuals (broad autism phenotype) and furthermore that some of these traits may be a manifestation of the liability to autism (Murphy et al. 2000; Piven et al. 1997).

In summary, little is yet known about the epidemiology of comorbidity patterns with ASD and PD.

Natural History, Prognostic Factors, Outcomes

In general, comorbidity with personality disorders becomes manifest in adolescence. In the current system of DSM 5, ASD often presents with symptoms that also address the criteria for a PD. This may cause confusion, however, when the first symptoms of ASD occur in adulthood. ASD can then be mistaken for a personality disorder, and vice versa, depending on the focus of the clinical assessment. Intelligence is an important prognostic factor in ASD (Seltzer et al. 2004), meaning that children with higher IQs have a better functional outcome in adulthood than those with lower IQs. Although it is possible that this is also the case in ASD comorbid with PD, clinical practice indicates that there are adults with ASD and high IQs whose functioning is severely hampered by comorbid personality traits. The outcome of ASD with PD has, however, not been studied in a systematic way. The clinical evidence suggests that, like in other symptom disorders, the presence of a PD in ASD increases the burden.

Clinical Expression and Pathophysiology

In ASD, impaired information processing in the brain is especially invalidating in complex situations involving social interaction and emotional communication. In addition, the insight in mental processes of others, but also the self, is often limited because of an impaired intuitive understanding of social relationships and contextual conventions. This implies that people with ASD require more time to evaluate (social) situations because cognitive compensation strategies are utilized to understand what people without ASD know without consciously thinking (Frith 2003).

The developing personality is also influenced by environmental factors, like in ASD. In this respect, the presence of ASD contributes to a pertinent environmental factor because impaired communication and difficulty interpreting social contexts lead to negative reactions of others, which in turn lead to avoidance, anxiety, or a lack of flexibility. The adverse experiences with social interaction may accentuate schizoid, avoidant, or dependent traits when looked at from the personality perspective. The impaired information processing and difficulty with correctly evaluating social contexts in ASD make a clear demarcation between reality and fantasy difficult, enhancing schizotypal personality traits (Towbin 2005). Early trauma and insecure attachment are risk factors for developing a borderline personality disorder (Fonagy and Bateman 2008). When a person with autism is exposed to these risk factors, the resulting phenotype can resemble both disorders. The overlap in phenomenology of ASD and borderline personality disorder, both characterized by altered social cognition, has been noted for some time (e.g., Dudas et al. 2017).

On the other hand, extremes in temperament that are distinctive of personality disorders can color the clinical picture of ASD. Social typologies used in ASD like “active but odd” are in part an expression of personality traits.

Evaluation and Differential Diagnosis

In the assessment, a reliable developmental history is mandatory to diagnose or rule out ASD and to

find evidence for causal factors that could contribute toward the development of the personality disorder. An assessment of personality should also be a part of the ASD assessment. Early trauma, insecure attachment (Fonagy and Bateman 2008) in the case of borderline personality disorder and an arrested developmental phase in the case of narcissistic personality disorder (Fernando 1998) are among the descriptive etiological hypotheses.

The assessment can lead to a classification of ASD and/or a PD. However, more informative is a comprehensive descriptive diagnosis in which traits and behavior, neuropsychological and other impairments, and an overview of contributing (causal) factors combine to serve as an explanatory model for the patient, his close relatives, and the clinician.

Treatment

In case of ASD comorbid with a PD, the effect of programs for personality disorders can be seriously reduced if no account is taken of the impairments that accompany ASD. For example, exposure therapy for social anxiety in an avoidant PD will be less effective when the origin of the avoidance is rooted in a fundamental inability to understand the other in social encounters, as in ASD. In fact, it may for some patients even be considered undesirable to change the avoidant behavior in autism as this could, in the worst case, deteriorate functioning by inducing more (disturbing) social stimuli.

In ASD comorbid with borderline personality disorder, clinical in-patient settings can undermine the autonomy of the individual, leading to serious regression with self-harm and aggressive behavior. Here, the clinical dilemma is between insisting that the patient takes her own responsibility (autonomy) while bearing in mind the cognitive and affective impairments resulting from ASD that prevents her from fully taking this self-responsible stance.

There is currently no systematic evidence to guide treatment of ASD comorbid with a PD or with prominent personality traits. Understanding the impairments (and adaptive aspects) of the individual is the best approach to tailor treatment. This

requires a clinician to be familiar with treatment programs for personality disorders and to study the ins and outs of ASD in order to be able to adopt the content or pace of the programs targeting the comorbid PD. Unadjusted PD treatment in patients with ASD probably has a high failure rate, although this had not been systematically studied.

PIC

Description

The Personality Inventory for Children, or PIC, is used to assess the emotional, behavioral,

cognitive, and interpersonal adjustment of children from kindergarten to 12th grade (Lachar and Gruber 2007). It is a series of statements that the parent or guardian rates as true or false in relation to their child. The goal of this clinical assessment tool is to learn more about the child and his or her problems in order to recommend clinical treatment (Sattler and Hoge 2006). It is used in a clinical and school setting.

Historical Background

Introduced in 1956 by Robert D. Wilt, the original 600-question booklet has gone through extensive testing and revision. After the first introduction, and extensive reliability testing, the PIC was altered in 1973. Thirteen questions that could be interpreted as offensive were removed (Lachar 1982). The first version of the PIC was officially published in 1977 (Sattler and Hoge 2006). It is currently in its second version, which is referred to as the PIC-2 (Lachar 1982). The normative tables and scores for the PIC-2 were derived from tests done on two samples of 2306 parents of children; Children in these samples were in Kindergarten through 12th grade, resided in 12 states, attended both urban and rural schools, and included 1551 parents of children who had been referred for clinical support (Personality inventory for children 2007). It takes approximately 40 min to an hour for a parent or guardian to complete the PIC-2. It also has a shortened form called the Behavioral Summary (Sattler and Hoge 2006). The Behavioral Summary contains only 96 items and can be completed in 15 min (Sattler and Hoge 2006).

Psychometric Data

The PIC-2 is comprised of 275 true or false questions (Lachar and Gruber 2007). The test-retest reliability rate is 0.82–0.92 with internal consistency rate of 0.81–0.92 (Lachar and Gruber 2007). There are 9 scales, composite scales, and 21 subscales in the PIC. The test can be administered

as a whole, administering only the Behavioral Summary, or administering the subscales that comprise the composite scores. The following scales and subscales, presented with brief descriptions, comprise the PIC-2:

Cognitive Impairment (COG)

Questions on the Cognitive impairment scale assess the child's difficulty in thinking or processing information (Molano 2010). There are three subscales in Cognitive Impairment in the PIC. Each subscale has 13 questions (Herson 2004). The first subscale is called Inadequate Abilities. This is designed to measure how the parent/guardian feels their child understands information in their environment. The second subscale within Cognitive Impairment is Poor Achievement. This is designed to measure how the parent/guardian feels about the child's performance in their school setting (Herson 2004). The third subscale is Developmental Delay. This is designed to measure how the parent/guardian evaluates specific developmental milestones, such as riding a bike or talking (Herson 2004).

Impulsivity and Distractibility (ADH)

Impulsivity and Distractibility has two subscales. The first subscale is Disruptive Behavior. Disruptive Behavior consists of 21 questions about how the child is able to focus on tasks in multiple settings (Herson 2004). The second subscale measures Fearlessness. It contains nine questions that address how the child would respond to dares, challenges, or other possibly dangerous situations (Herson 2004).

Delinquency (DLQ)

Delinquency is the lack of conformity to social norms. Delinquency has the following three subscales: Antisocial Behavior, Dyscontrol, and Non-compliance. Antisocial Behavior has 15 questions regarding how the child behaves in social situations (Herson 2004). Dyscontrol, or regulation of behavior (Grigsby et al. 1992), which has 16 questions, is designed to assess how the parent interprets their child's behavior in social situations (Herson 2004). Noncompliance has 11 questions

that focus on how the child responds to rules and consequences (Herson 2004).

Family Dysfunction (FAM)

Family Dysfunction has the following two subtests: Conflict Among Members and Parent Maladjustment. Conflict Among Members has 15 questions about the relationship of family members and the strategies that they employ to deal with different family situations (Herson 2004). Parent Maladjustment has 10 questions that focus on how parents deal with stress (Herson 2004). For example, there is an item about parent drinking habits on the Parent Maladjustment subscale (Herson 2004).

Reality Distortion (RLT)

Reality Distortion has the following two subscales: Developmental Deviation and Hallucinations and Delusions. Developmental Deviation has 14 questions about how the child perceives everyday dangers (Herson 2004). Hallucinations and Delusions has 15 questions about the child's level of paranoia (Herson 2004).

Somatic Concern (SOM)

Somatic Concern has the following two subtests: Psychosomatic Preoccupation and Muscular Tension and Anxiety. Psychosomatic is a physical ailment caused by mental processes, stress, or unhappiness (Shorter 1992). Psychosomatic Preoccupation is measured by 17 questions about how the child perceives or feels illness (Herson 2004). Muscular Tension and Anxiety has 11 questions about how often the child feels stress-related pain or other physical symptoms of stress (Herson 2004).

Psychological Discomfort (DIS)

Psychological Discomfort is comprised of the following three subtests: Fear and Worry, Depression, and Sleeping Disturbance/Preoccupation with Death. Fear and Worry has 13 questions about how child handles unknown situations (Herson 2004). Depression has 18 questions about how the child expresses emotions (Herson 2004). Sleeping Disturbance/

Preoccupation with Death is measured with 8 questions about how the child sleeps and whether the child evidences any suicidal thoughts or tendencies (Herson 2004).

Social Withdrawal (WDL)

Social Withdrawal has the following two subtests: Social Introversion and Isolation. Social Introversion has 11 questions about the child's shyness and social competence (Herson 2004). Isolation has eight questions regarding the child's social preferences. For example, Isolation addresses whether the child stays in rooms most of the time (Herson 2004).

Social Skill Deficits (SSK)

Social Skill Deficits has the following two subscales: Limited Peer Status and Conflict with Peers. Limited Peer Status has 13 questions about the child's social standing with peers, types of friendships, and number of friends (Herson 2004). Conflict with Peers has 15 questions about how other children react socially to their child (Herson 2004).

Composite Scales

The PIC has the following three composite scales: Externalizing, Internalizing, and Social Adjustment. The Externalizing composite scale focuses on disruptive behavior and inattention. It is measured in the PIC by adding the scores of Impulsivity and Distractibility and Delinquency (Herson 2004). The Internalizing composite scale focuses on negative cognitions, feelings, and emotions. It is computed by adding the scores from Reality Distortion and Somatic Concern (Herson 2004). The Social adjustment composite provides a measure of overall social adaptation. It is computed by adding the Social Withdrawal and Social Skill Deficits (Herson 2004).

Composite scales can be used to look at one aspect of the child's behavior. For example, a researcher could use a selection of subscales to assess one area of a child's abilities (e.g., social adaptation). Researchers often use composite scores when their research does not require all of the information that is collected in the full PIC-2.

Clinical Uses

In the past, clinicians used the PIC to separate children who needed clinical support into the following six groups: Delinquent, Hyperactive, Cerebral Dysfunction, Somatizing, Mental Retardation (now termed intellectual and developmental disability), and Psychotic (Lachar et al. 1982). Cerebral Dysfunction is also known as brain damage. Somatizing is a physical illness due to stress, unhappiness, or other mental processes (Molano 2010). Currently, the PIC-2 is used to obtain a profile of a child's problem behaviors along with indicators for family dysfunction.

The PIC has been used in a wide range of research projects. For example, it has been included in studies of child achievement (Gough 1946), effects of behavioral treatment for children with autism (Sallows et al. 2005), psychosocial effects of siblings of children with Autism and Mental Retardation (Bagenholm and Gilberg 1991), Psychosocial adjustment of refugees (Rohr 1996), and anxiety studies. In Autism research, the PIC-2, along with other diagnostic tests, is administered before behavioral intervention and re-administered after intervention to understand whether behavior therapies have had an impact on social and emotional aspects of a child's behavior. The PIC-2 can also be used to determine eligibility of participants for a research study.

Personality Structure in Autism Spectrum Disorders

► Personality Disorders

Personality, Clinical Assessment

Marjorie Solomon

Department of Psychiatry and Behavioral Sciences, UC Davis M.I.N.D. Institute, Sacramento, CA, USA

Definition

Clinical assessment is an evaluation of a patient's physical condition and prognosis based on information gathered from behavioral, physical, and laboratory examinations and the patient's medical history (Mosby 2009). Psychologists or physicians typically assess and diagnose autism spectrum disorders. These clinicians generally are trained as clinical or educational psychologists, psychiatrists, behavioral and developmental pediatricians, and neurologists. Specialized speech and language pathologists and occupational therapists also may provide ASD evaluations. Gold standard assessments consist of thorough parent and child interviews about history and current behavior, consider the role of development, and employ standardized measures.

Historical Background

Practice parameters for ASD assessment have been published by the American Academy of Neurology (Filipek et al. 2000), by the American Academy of Child and Adolescent Psychiatry (Volkmar et al. 1999), and by a consensus panel with representation from multiple professions (Filipek et al. 1999). Each describes two levels of screening consisting of routine developmental surveillance that provides services for young children (i.e., pediatricians) and more comprehensive diagnostic assessment by experienced clinicians for children who fail screening. Prior to the issuance of these practice parameters, oral traditions and subjective observations dominated the assessment of ASD.

The publication of two standardized assessment tools – the parent interview known as the Autism Diagnostic Interview-Revised (ADI-R; Lord et al. 1994; Rutter et al. 2003) and the observer rated semi-structured play interview known as the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000), also resulted in greatly standardized and reliable ASD diagnoses. These measures currently are considered the “gold standard” in ASD diagnosis. They both require specialized training to administer.

Current Knowledge

A thorough clinical assessment of the child with ASD includes multiple steps. The first of these is to review the child's developmental history and the parents' current concerns. This history must include the review of communication, social and behavioral development, and screening for comorbid medical and psychological conditions including anxiety and depression, and attention deficit symptoms. A review of existing records (medical, school, previous testing, and intervention reports) rounds out the perspective provided by the parent interview. In addition to the history, good assessment includes observation of the child. If possible, this observation should be supplemented by teacher reports of child functioning in the less-structured school setting.

As mentioned above, one of the “gold standard” autism measures – the ADI-R – can be used to interview the parent about the development of autism symptoms in their child. ADI-R is a semi-structured interview that takes approximately 3 h to administer. The much briefer Social Communication Questionnaire (Berument et al. 1999) is a parent-report instrument that contains the same questions as are used to make a diagnosis on the ADI-R, but they are presented in yes/no format and parents can complete it on their own.

The other “gold standard” instrument, the ADOS is a semi-structured interactive play-based assessment of symptoms. It consists of four age and language-graded modules containing

social “presses.” Module 1 is used with children who do not consistently use phrase speech, module 2 with those who use phrase speech but are not verbally fluent, module 3 with fluent children, and module 4 with fluent adolescents and adults. Activities used in ADOS modules 1 and 2 are designed to assess joint attention, communication, symbolic play, and atypical behaviors (restricted and repetitive behaviors and sensory interests) and consist of toy, bubble, and pretend play, reading simple books, and participating in common social scripts like a birthday party. Activities used in modules 3 and 4 assess conversation skills, empathy, and insight into social relationships and include reading books, discussing pictures, engaging in pretend play with toys and objects, acting out stories presented in pictures, and discussing one's feelings, social relationships, and school and/or work situation. Participants are rated based on their level of social interaction and social language, taking their chronological age into account.

In addition to the assessment of ASD symptoms, a good clinical evaluation should include measurement of cognitive abilities. This is important because cognitive level often influences the expression of autism symptoms and may be associated with the ability to acquire skills and the individual's potential level of adaptive functioning. Longitudinal studies also suggest that cognitive ability level is the best predictor of long-term outcome for persons with ASD, with those with intellectual disability typically faring worse. Studies also consistently point out that, even in persons with ASD with cognitive abilities in the average range, adaptive functioning tends to lag behind. Recently, it also has been demonstrated that persons with autism and Asperger syndrome perform better on intelligence tests that assess their perceptual reasoning abilities (Raven's Progressive Matrices) versus more language-based tests like the Wechsler Scales. There also are tests that are more appropriate for children with lower mental ages like the Leiter International Performance Scales-Revised (Roid and Miller 1997). For children less than 5 years of age, the Bayley Scales of Infant Development-II (Bayley 1993) and the Mullen Scales of Early Learning (Mullen 1995) can be used.

After IQ, expressive language ability is the most consistent predictor of outcomes. Those who fail to develop spoken language by early childhood (age 5 or 6) tend to remain minimally verbal, although there have been recent advances that challenge this widely held assertion. There are many general language tests that can be used to provide a clearer picture of expressive and receptive language abilities. Two such tests are the Peabody Picture Vocabulary Test (Brownell 2000) and the Clinical Evaluation of Language Fundamentals (Semel et al. 2003).

However, even when children with autism have adequate spoken language, they frequently demonstrate challenges with language pragmatics or social language, which involves:

Using language for different purposes, like greeting, informing, demanding, and requesting.

Changing language according to the needs of a listener and/or the situation like talking differently to a child than to an adult, providing background information to an unfamiliar listener, and following topic and reciprocity norms for conversations (turn taking, appropriate topics, staying on topic).

Individuals with pragmatic language problems may say inappropriate or unrelated things during conversations, tell stories in a disorganized manner, and without meaning to, say things that are blunt or offensive. It is difficult to assess pragmatic language, and not all speech and language pathologists are equipped to do so. There are several measures developed to assess this form of language. They include the Test of Language Competence (TLC; Wiig and Secord 1989), which is administered by a trained professional, and the Children's Communication Checklist-2 (Bishop and Baird 2001), which is a parent, teacher, or other caregiver report questionnaire that assesses aspects of language pragmatics.

Adaptive behavior is the final domain that should be assessed in a comprehensive evaluation. To make a diagnosis of intellectual disability, information about functioning must be considered alongside information about cognitive ability level. Furthermore, knowing about an individual's adaptive functioning is important for setting appropriate treatment and educational goals.

In individuals with ASD, the most widely used measure of adaptive functioning is the Vineland Adaptive Behavior Scales (Sparrow et al. 1984). It assesses functioning in domains of communication, daily living skills, socialization, and motor skills (under age 5). It is a parent or teacher report interview. There are also several questionnaire-based measures of adaptive functioning including the Adaptive Behavior Assessment System (ABAS; Harrison and Oakland 2003).

There are several domains that frequently also are assessed beyond this core diagnostic battery. A neuropsychological assessment may provide greater clarity about the individual's pattern of strengths and challenges in information processing. This can provide valuable information for schools and transition planning. Neuropsychological assessments in autism frequently focus on executive functions, and selective attention, and generally are administered by the examiner. Recently, more investigators and clinicians are using the Behavioral Rating Inventory of Executive Function (BRIEF; Gioia et al. 2000). This parent- or teacher-rated questionnaire measures inhibition, cognitive flexibility, organization, planning, metacognition, emotional control, and initiation. A neuropsychological assessment also may examine whether the individual displays a nonverbal learning disability profile (Rourke 1995). Children with this profile exhibit well-developed rote verbal skills, verbal memory, and auditory learning capabilities, but have problems with psychomotor coordination, math problem solving, and visuospatial organization. Some children with Asperger syndrome are thought to display this set of strengths and challenges.

Academic assessments can provide additional school-relevant information. Children with ASD have many relative academic strengths related to reading decoding and memory for facts (especially those about their circumscribed interests). Others may possess strong math and/or computer skills. Alongside these strengths, however, they frequently display deficits in reading comprehension, expository writing, and mathematics story problems. It takes considerable skill to tear apart this pattern of strengths and challenges. An understanding of such information is

essential for helping affected individuals to achieve their potential.

Finally, as mentioned above, it is important to assess comorbid psychiatric conditions in individuals with ASD. Approximately 30–40% of them display symptoms of anxiety, depression, and behavioral problems. These can be assessed using instruments from the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach 2009) or the Behavioral Assessment System for Children (BASC-2; Kamphaus et al. 1999). The psychosocial and cognitive symptoms found in autism can make it difficult to diagnose psychopathology in individuals with ASD. For example, their restricted and repetitive behaviors may intensify during periods when they are anxious – a symptom of anxiety not found as commonly in the general population.

Although DSM-IV-TR does not permit the diagnosis of attention deficit hyperactivity disorder (ADHD) symptoms in persons with ASD, in reality, attention symptoms are present in about half of them. This precedence rule is likely to change in DSM 5. ADHD symptoms can be assessed using the Conners Scales.

Finally, when assessing autism, it is critical to maintain a developmental perspective as symptoms change with age. For example, what would be considered a normal level of reciprocal conversational ability for a young child would be quite different than that of a teenager. Similarly, normal levels of overactivity also decline with age.

Future Directions

Assessment-related research and information are badly needed in several areas. First, given what is known about the benefits of early intervention, one critical area is improving our ability to diagnose autism very early. Diagnosis should be across multiple settings and leverage the perspectives of multiple types of service providers. At the present time, considerable research dollars are being spent on developing early behavioral and biological markers of ASD.

Second, as mentioned above, it has been demonstrated that persons with autism and Asperger

syndrome perform better on intelligence tests that assess perceptual reasoning abilities (i.e., Raven's Progressive Matrices) versus more language-based abilities that are tapped in more commonly used measures such as the Wechsler Scales. Additional work is needed to better understand this finding and to use results to help design more comprehensive estimates of the strengths in the cognitive abilities of individuals with ASD and intellectual disability who are nonverbal.

Third, there are several areas that warrant the development of new, more comprehensive and ecologically valid assessment instruments. These include pragmatic language, treatment efficacy, cognitive flexibility, and social skills measures. Better measurement of these areas would provide excellent information for treatment planning.

Finally, as in many areas of autism research, we know little about adults with the disorders. Better measures are needed to diagnose autism in adulthood in individuals with higher levels of functioning. The field also currently lacks good and specific measures of functional outcomes for this population.

Person-First Language

Corey Ray-Subramanian
Waisman Center, University of Wisconsin-
Madison, Madison, WI, USA

Synonyms

People-first language

Definition

Person-first language is a method of referring to individuals with disabilities, medical conditions, or functional impairments that emphasizes the person over their disability, condition, or impairment. The term “a child with autism” would be consistent with person-first language, whereas the term “an autistic child” would not. Proponents of person-first language assert that individuals with disabilities should not be defined by their disabilities to avoid dehumanization and equating the individual with his or her impairment (Folkins 1992; Research and Training Center on Independent Living 2008; Smart 2001). However, some disability self-advocacy groups do not prefer person-first language when referring to members of their group, as they do not necessarily view their labels as disabilities, characteristics of which to be ashamed, or traits that can be separated from themselves as individuals (Autistic Self-Advocacy Network Australia n.d.; Smart 2001; Streeter 2010).

Pertussis and Autism

Paul A. Offit
Division of Infectious Diseases, Department of
Pediatrics, The Children’s Hospital of
Philadelphia, Philadelphia, PA, USA

Definition

On April 19, 1982, a local NBC affiliate in Washington, DC, aired a 1-h documentary titled *DPT: Vaccine Roulette*. The program featured the stories of several children: all had received the whole-cell pertussis vaccine and all had

subsequently developed epilepsy and mental retardation. Several parents who watched this show – and collectively believed that their children’s developmental delays were caused by pertussis vaccine – formed an advocacy group called “Dissatisfied Parents Together.” By the early 1990s, this group changed its name to the National Vaccine Information Center, one of the most powerful anti-vaccine organizations in the United States.

The head of the National Vaccine Information Center, Barbara Loe Fisher, later wrote a book titled *A Shot in the Dark: Why the P in the DPT Vaccination May be Hazardous to Your Child’s Health*. In that book Fisher wrote, “With the increasing number of vaccinations American babies have been required to use has come increasing numbers of reports of chronic immune and neurological disorders being suffered by older children and young adults including asthma, chronic ear infections, autism, learning disabilities, attention deficit disorder, diabetes, rheumatoid arthritis, multiple sclerosis, chronic fatigue syndrome, lupus, and cancer.” This book gave birth to the notion that vaccines, especially the pertussis vaccine, could cause developmental delays, including autism.

During the next 10 years, several groups of investigators examined children who either had or had not received pertussis vaccine to determine whether there were differences in the incidence of developmental delays or epilepsy in the two groups. All investigators found that the pertussis vaccine did not cause permanent neurological damage. In 2006, a neurologist working at the University of Melbourne in Australia, using genetic tools that had only recently become available, found that many children whose parents had claimed that pertussis vaccine had caused brain damage actually had a neuronal sodium channel transport defect, specifically, an SCN1A mutation. One hundred percent of children with this mutation will develop seizures and developmental delays in the first year of life independent of vaccination. From the standpoint of scientists, the combination of epidemiological and biological studies put an end to the notion that the whole-cell pertussis vaccine, which has not been used in the United States since the mid-1990s, caused permanent harm.

Pervasive Developmental Disorder

Oana De Vinck

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Autism spectrum disorders](#)

Definition

Pervasive developmental disorders are a group of neurodevelopmental conditions and include autistic disorder, Asperger's disorder, childhood disintegrative disorder, and Rett's disorder. These disorders are characterized by some or all of the following: significant social skills deficits, language abnormalities, restricted interests, and repetitive motor mannerisms. Although there is a strong genetic basis for all except Rett's disorder, the precise genetic cause has not been delineated. Typically, the diagnosis of these conditions is made clinically on the basis of characteristic developmental criteria described in the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition Text Revision* (DSM-IV-TR). These diagnoses have a wide range of symptom complexes that are within the scope of the spectrum, and children vary widely in abilities, intelligence, and behavior.

Synonyms

[PDDRS](#)

Description

The PDDRS is a behavior rating scale designed to identify individuals potentially meeting criteria for a pervasive developmental disorder (PDD). It

was developed by Eaves (1990; Eaves and Hooper 1987–1988) and contains 51 items that measure three dimensions: arousal, affect, and cognition. The “arousal” domain contains 22 items dealing with avoidance of others, sensory stimulation, and fascination with objects; “affect” includes 19 items concerning aggression, fear, anxiety, or distorted affect; and “cognition” contains 10 items regarding speech and language, skill development, and savant skills. Raters are requested to answer each item using a five-point Likert scale according to the degree to which the child generally shows the behavior described. The total score is obtained by summing the separate scores for each subscale. Raw scores can be transformed into standard scores and percentile ranks as an indicator of autism symptoms.

Historical Background

The PDDRS was developed in the early 1990s by Ronald Eaves of Auburn University based on his theory that central nervous system processing in all humans, including those with PDD, can be reduced to three internal processes: arousal, affect, and cognition (Eaves 1993). The author attempted to utilize his theory of human behavior to adapt DSM-III-R criteria into a measure for indexing PDD. The integrated theory of human behavior suggests that individuals with PDD, in addition to individuals with other disabilities, experience problems in one or more of these three internal human attributes. As such, the scale attempted to identify PDD through alterations in these attributes. The items were selected based on the developer’s theory, a review of clinic files of individuals with PDD, as well as existing instruments and DSM-III-R criteria for PDD.

Psychometric Data

Published psychometric data regarding the PDDRS from research groups not directly affiliated with the primary author is very limited (Eaves 1993). According to the instrument developer, the PDDRS was initially normed on a

sample of 500 individuals diagnosed with PDD. The authors purported high initial levels of internal consistency (.92 total score) and high test-retest reliability over short intervals of time. Data from the same sample suggested less robust reliability characteristics with varying raters over longer periods of time. Final instrument structure was also reportedly based on a factor analysis within this same sample of 500. Subsequent studies from groups affiliated with the test developer have demonstrated substantial agreement with other measures, including the Autism Behavior Checklist (see Eaves et al. 2000) and the Gilliam Autism Rating Scale (see Eaves et al. 2006). Limited data regarding the ability of the instrument to discriminate autism spectrum disorders from other complex neurodevelopmental disorders is available.

Clinical Uses

The PDDRS is a rating scale administered to caregivers and designed to be a screening instrument for autism. It is not currently in wide use in either clinical or research settings. The author/developer discourages the use of the instrument for eligibility determinations.

Pervasive Developmental Disorders Screening Test (PDDST)

Bryna Siegel
Autism Clinic, Department of Child and Adolescent Psychiatry, University of California, San Francisco, San Francisco, CA, USA

Synonyms

[Pervasive Developmental Disorders Screening Test-II \(PDDST-II\)](#)

Description

The PDDST-II is validated for early screening of autistic spectrum disorder (ASD) in children 18 months to 48 months of age based on both positive signs (symptomatic behaviors) and negative signs (delayed milestones) weighed in a manner that numbers of specific signs additively yield a sensitive and specific screen. The PDDST-II is designed around three key principles: First, parents are uniquely positioned to report on both

habitual as well as low-frequency behaviors that may correlate with an ASD, so they are the best starting point for diagnostic identification process; second, parents of a not-yet-diagnosed child will be inexpert in calibrating quality and severity of reported behavior in the same manner as a skilled clinician, so screening must include a clinician-validated final scoring; and third, a screener should aim to minimize false positives both for humane reasons and for diagnostic efficiency.

Historical Background

Development of the PDDST began in 1986 as an effort to create a brief screen for autism that would be helpful in recognizing autism across (1) primary care settings, (2) specialized developmental care settings, and (3) tertiary diagnostic clinics specializing in autism spectrum disorders. It was clear from the outset that the contrast populations in which potential cases would be embedded would be very different in each of these three settings, and therefore, the sensitivity and specificity of screening items would vary depending on the contrast population. The plan was to test a pool of items and examine relative predictive validity in each of the three settings in index and contrast populations. Items with highest predictive validity in each setting would be retained as screener items and assigned to the screener where the item had high predictive validity. Items with high sensitivity but low specificity (but overall lower predictive validity) would be retained as descriptive items.

Data collection began at the Stanford Autism Clinic in 1986, where a pilot screener was completed for all clinically referred cases under age 5. When the author moved to UCSF in 1989, data collection carried on there until approximately 2005. In addition, in the early 1990s, a comparison group of toddlers who had been very low birth weight (<1,000 g) and experienced neonatal intraventricular hemorrhage (VLBW/IVH) were sampled at 2 years of age as a “developmentally at high-risk, but not specifically autism-risk,” contrast group. Ultimately, the stage 1 screening for pediatric clinics was normed on the all clinically autism-referred cases against the VLBW/IVH

cases as it was felt that overall sensitivity of an instrument that detected no-risk children from autism-referred children would lack specificity. The stage 2 screener for developmental clinics was normed within the population of ASD-referred cases with the index sample being confirmed ASD cases and the contrast population being those for whom an ASD had been ruled out. The stage 3 severity screener which aimed to identify more from less severe cases of autism based on these early signs used autism-confirmed cases as the index population and non-autistic disorder ASD as the contrast population.

An initial version of the three-stage PDDST was compiled in 1991. Data analyses reported in the late 1990s and early 2000s reflect work on this initial version (essentially the PDDST-I), and then in 2004, the final data set with revised psychometrics plus the manual, glossary, and supplemental items (those not included in stage 1 or 2 or 3 but highly sensitive) was compiled and published by PsychCorp as the PDDST-II. The manual gives the psychometrics for the final sample of over 1,000 cases, and the glossary is an item by item inventory of the qualities, thresholds, and examples for each item and is intended for the clinician who scores the parent-completed form to use and to validate a parent-reported positive screen – before referring the child on for further assessment.

Psychometric Data

The PDDST-II Kit (consisting of the technical manual, scoring glossary, and three stages of screeners) (in English or Spanish) is available at <http://www.pearsonassessments.com/haiweb/cultures/en-us/productdetail.htm?pid=076-1635-106&mode=summary>.

Depending on the clinical or research application, one or more stages of screening can be used together. Questions on each screener are organized by age at which the sign/item has typically been reported present. Table 1 shows numbers of items, cutoff number, and sensitivity (Se) and specificity (Sp) for each screener stage.

The PDDST-II Stage 1 Primary Care Screener was shown to be very efficient, with few false

positives (<10%), correctly classifying over 90% of cases that had been clinically screened to an autism-specific clinic after extensive telephone screening. The PDDST-II was validated on 977 cases (N of ASD = 519, N of non-ASD = 458), including ASD-confirmed, ASD-referred, and VLBW control cases. Table 2 gives examples of key items for each screening stage. Importantly, unique (high Sp) items were readily identifiable in analyses that contrasted clinical (telephone) screened ASD-positive cases from a sample of at-risk cases (VLBW) Ss. At stage 2, when ASD-assessed positive cases were contrasted with ASD-assessed negative cases, specificity was more difficult to ascertain than sensitivity, as was the case when examining signs within the ASD-positive population for indicators of severity based on early signs. Table 2 shows exemplar items at each screening stage.

The PDDST-II Glossary – When the parent submits a positive PDDST-II screen, the clinician

Pervasive Developmental Disorders Screening Test (PDDST), Table 1 Item # cutoffs, Se and Sp by screening stage in norming sample

Stage	Cutoff	Se	Sp	N
I	5/22	0.92	0.91	577
II	5/18	0.73	0.49	379
III	8/13	0.58	0.60	260

Pervasive Developmental Disorders Screening Test (PDDST), Table 2 Sample items by stage of screener

Stage	Item	
	Se	Sp
<i>Stage I: primary care screener</i>		
Seems bored or uninterested in conversations around him	0.79	1.0
Alert to some sounds but not to others	0.68	1.0
Ignores new toys	0.60	1.0
<i>Stage II: developmental clinic screener</i>		
Cries when left, does not greet upon reunion	0.38	0.87
Not using gestures to communicate	0.47	0.83
Fixates on fingers	0.31	0.87
<i>Stage III: autism versus PDD (severity) screener</i>		
Not interested in peers	0.88	0.26
Uninterested in talking	0.82	0.23

is directed to the PDDST-II glossary which contains specific verbal probes to query the parents’ response to each positive item to validate that the parent has understood the definition, qualities, and threshold at which this item should be considered truly positive. If a positive score remains after clinician validation, a referral for an ASD assessment is supported; see Table 3.

Supplemental Descriptive Items – In addition to items contained on the three screener stages, there are 41 additional items that characterize common parental observations about delays and atypical development in young children with autism. These additional items are not useful in predicting a positive screening score on stage I, II, or III (mainly because they reflect concerns common, but not unique to ASD) but do provide a more full picture of parental concerns and may be useful, especially where time constraints mandate obtaining a concise, highly focused parent-reported developmental history. While low in specificity, the supplemental items also may help identify a differential diagnosis to pursue in further assessment; see Table 4.

Clinical Uses

Insuring Clinical Validity

The key issue in the development of any screening test is to be useful by detecting cases and at-risk

cases readily, but not so readily that there is a high false-positive rate, rendering the screener highly inefficient. The first “cut” in collection of effective screening data is often reliance on the effected individual (or as is the case in autism, the parents). Parents can underreport because of lack of familiarity with child norms or because of fear of the consequences of a positive screen. Likewise, parents may overreport if a positive screen is seen as leading to more clinical attention – and that is deemed a good thing. The second “cut” therefore is validation of the reporter. In screening, it is desirable if the validation can quickly and efficiently be done on the site of screening. The PDDST utilizes a glossary for the administering clinician to check items reported with positive scores by reading a few sentences about the qualities linked to an autism diagnosis (specificity) and needed threshold for the item to reach clinical significance. For each item, the glossary provides verbatim probes the clinician can use to elicit further report that should clarify whether the positive score is a valid one. Likewise, an item the parent reported as negative but observed as potentially positive by the clinician can be further probed using guidance from the glossary.

Pervasive Developmental Disorders Screening Test (PDDST), Table 3 Sample PDDST-II glossary entry

If you talked to your baby in baby talk, was it hard to get him to “talk” back to you?
<i>Qualities:</i> This measures prelinguistic communicative reciprocity, the first component of which is vocal turn-taking. It is like an early “sound check” that tells us the baby can hear, process what he hears, and reproduce it with some accuracy.
<i>Threshold:</i> By the end of the first 6 months, most parents know some sounds that they can sometimes get their baby to repeat back once or more when the baby is “in the mood.”
<i>Probe for:</i>
Babbling of prespeech sounds
Ability of baby to anticipate and wait for a parent response

Pervasive Developmental Disorders Screening Test (PDDST), Table 4 Sample supplemental items (one sample item per age group)

Birth to 6 months
1. Did your baby seem to stare too much at moving objects or moving lights?
6–12 Months
4. Did your baby not show he/she wanted to go “up” with his/her arms – even when he/she was fussing to be picked up?
12–18 Months
5. Did your baby only rarely or never babble?
18–24 Months
16. Did your toddler ever pose or wave his/her fingers or hands when excited?
24–30 Months
24. Would your toddler pull you to a desired object as his/her way of showing you what he wanted?
30–36 Months
38. Did your child seem more of a perfectionist than other children his/her age?

Three Clinical Settings for the Identification of ASDs

The PDDST-II has been developed for use in three different clinical settings where children with ASD are regularly seen because children with ASD will be compared to different samples of other children depending on where they are assessed. *Stage 1 Primary Care Screener* is for use in primary care settings where children with ASD need be distinguished from among all children of the same age, so screen-positive children can be referred to specialized developmental assessment centers. *Stage 2 Developmental Clinic Screener* is for point of entry to developmental services (Child Find, Early Start, special education, or Department of Developmental Services or Public Health) where children with ASD will need to be distinguished from other children at risk for some neurodevelopmental disorder, so screen-positive children can be referred for more extensive (and costly) confirmatory assessment of an ASD. *Stage 3 ASD Severity Screener* is for use in an autism clinic where it may be helpful clinically or for research purposes to predict severity of ASD (e.g., AD vs. PDD, NOS) from early signs.

Referral for Assessment of Other Neurodevelopmental Disorders

If a positive result is *not* obtained on the PDDST-II, the next clinical question is “What instead might be the nature of this child’s difficulties?” Most commonly, children who screen ASD negative on the PDDST-II may have some form of transient developmental delay (especially under 2 years), overall intellectual disability, a receptive-expressive language disorder, an anxiety disorder, a severe attention deficit, or some combination of these. Additionally, very unstructured parenting combined with extreme temperamental variations, coupled with non-specific neurodevelopmental signs, can be very difficult to delineate from an ASD without in-depth assessment. This complexity speaks to the importance of not mistaking a screening test for comprehensive diagnostic assessment.

Children who do not screen positive for an ASD should be referred to another tertiary diagnostic clinic if something other than transient delay is suspected.

Phenocopies

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Definition

In some cases, particular phenotypes can be attributed directly to a specific known genetic change in an individual or family. When identical or very similar traits result from some other factor, including environmental causes, these traits or the individuals carrying them are called phenocopies.

A condition called “congenital cataracts” serves as a useful example of the difference between a phenotype and a phenocopy. Congenital cataract is a disorder in which children are born with clouded lenses in their eyes. In this condition, mutations in certain genes have been found to result directly in the phenotype-clouded lenses (Churchill and Graw 2011). These forms of congenital cataracts are often inherited. Sometimes, however, the same phenotype can result from an environmental cause that mimics the phenotype caused by the abovementioned specific genetic changes. For example, in utero infection by the Rubella virus can lead to clouded lenses in the absence of the genetic changes that lead to the inherited form of congenital cataracts (Churchill and Graw). The trait of having this form of congenital cataracts caused largely by an environmental factor or the individual with this form of congenital cataracts would be referred to as a “phenocopy.”

Phenocopies must be considered in efforts at gene discovery. For example, in certain types of genetic analyses, the a priori assignment of affected status within a family is an essential prerequisite. Here the presence of a phenocopy may lead to contradictory evidence with regard to the presence or location of a disease-related mutation. With regard to autism, certain factors such as drug exposures, “profound institutional privation,” (Volkmar 2005) or other conditions, such as congenital blindness and severe disorders of receptive

language (Brown et al. 1997; Volkmar 2005), may lead to ASD phenocopies.

Phenomenological Approach

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of
Child Psychiatry, Pediatrics and Psychology, Yale
Child Study Center, School of Medicine, Yale
University, New Haven, CT, USA

Definition

The term phenomenology has several different meanings (including an entire body of work within philosophy about ways of knowing the world). In medicine and science, it is more frequently used to refer to an approach in which empirical observation, rather than theory, plays a central role. Within psychiatry and medicine, this

approach has guided recent editions of the Diagnostic and Statistical Manual starting in 1980 with DSM-III. Prior editions of DSM had been strongly based in theory, but this complicated the usefulness of the classification schemes and, paradoxically, inhibited research. With DSM-III and subsequent editions, the emphasis has been less on theory-driven descriptions and much more on observable phenomena.

The emphasis on observable phenomena as opposed to theory has led to a dramatic increase in research. Theories have been developed over time using data gathered from phenomenologically based classification schemes. In reality, boundaries between theory and phenomenology can become blurry. Further, as Andreasen (2006) notes, unfortunately, this approach itself has tended to become somewhat reified with an overemphasis on the descriptions provided in DSM and a lack of attention to the entire context of the patient and context in which problems develop.

Phenothiazine

Lawrence David Scahill

Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA

Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA

Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Phenothiazines were the first type of antipsychotic medication introduced to the marketplace. This class of medications includes chlorpromazine (Thorazine), perphenazine (Trilafon), and fluphenazine (Prolixin) to name a few. These medications block dopamine receptors in particular brain areas. The blockade of these dopamine receptors is presumed to be the mechanism of action that reduces the hallucinations and delusions of schizophrenia. The success of these medications in reducing these so-called positive symptoms of schizophrenia had a major impact on mental health care worldwide. For example, the reduction of these disabling symptoms made it possible for individuals with chronic schizophrenia to leave institutions and be treated in outpatient settings.

Despite the major advance of the traditional antipsychotic medications, they are associated with adverse effects. Of particular importance are the neurologic adverse effects such as tremor, dyskinesia (abnormal movements), and dystonia during the acute phase of treatment. In some cases, dystonia can be an urgent adverse effect with neck stiffness and oculogyric symptoms (eyes tend to roll up backward into the eyelid). This is an acute situation and often quite disturbing to the patient. Dystonias, dyskinesia, and oculogyric crisis are treated with anticholinergic medications (► [Anticholinergic](#)). Long-term treatment with the traditional antipsychotics can also be associated with tardive dyskinesia, which is a potentially chronic movement disorder.

[Simple phobia](#)

Short Description or Definition

The DSM-IV-TR (American Psychiatric Association 2000) defines specific phobia as a “marked and persistent fear that is excessive or unreasonable, cued by the presence of a specific object or situation.” Exposure to the feared

stimulus must immediately provoke an anxiety response, and the individual must experience avoidance or intense distress that significantly interferes with his or her daily functioning.

Categorization

The DSM-IV-TR lists five categories of specific phobia: animal type, natural environment type (e.g., heights, storms, water), blood-injection-injury type, situational type (e.g., airplanes, elevators, enclosed places), and other type.

While the most common phobias in typically developing (TD) children are doctors, dentists, thunderstorms, and the dark (Muris et al. 1998), children with ASD have been found to have more phobias related to situations and to medical procedures (Evans et al. 2005). For example, the most common fears in children with ASD include needles or injections (De Bruin et al. 2007; Leyfer et al. 2006), the dark (De Bruin et al. 2007), and crowds (Leyfer et al. 2006). Fear of loud noises is also far more common in children with ASD than in TD children (Leyfer et al. 2006).

Epidemiology

Rates of specific phobia in the typically developing population are as follows: 5% of children in community samples have specific phobia, while 15–20% of children presenting to anxiety clinics have specific phobia (Gadow et al. 2004; Kessler et al. 2005; Ollendick et al. 2002).

Specific phobia is one of the most prevalent anxiety disorders in children with ASD (De Bruin et al. 2007; Leyfer et al. 2006; Muris et al. 1998; Sukhodolsky et al. 2008), with rates cited from 31% to 63% in school-age children and adolescents with ASD (De Bruin et al. 2007; Gadow et al. 2004; Leyfer et al. 2006; Muris et al. 1998; Sukhodolsky et al. 2008) and closer to 20% in preschool children with ASD (Gadow et al. 2004). Specific phobia also tends to be more severe in children with ASD than in TD children (Gadow et al. 2005). There is much less research focusing on anxiety disorders in adults with ASD, but Hofvander et al. (2009) found that

6% of adults with ASD and with normal intelligence had specific phobia.

Natural History, Prognostic Factors, and Outcomes

There is little research on prognostic factors or outcomes of specific phobia in ASD, but in typically developing populations, it is thought that genes, temperament, and environment contribute to the etiology and prognosis of specific phobia. Children with specific phobia are more likely to have parents with specific phobia, which may be due to both genetic factors and parenting style (Ollendick et al. 2002). For example, parents with phobias may be more likely to set an example of phobic avoidance and/or be overprotective towards their children, which may increase the likelihood of their children developing specific phobia (Ollendick et al. 2002). Temperament also appears to play a role: children who have inhibited temperaments are at elevated risk for developing specific phobia. Those whose inhibited temperaments are stable between about 2 and 7 years develop specific phobia at rates close to 50% (Kagan et al. 1987, 1988). Children with ASD have been found to have more withdrawn and less adaptable temperaments than typically developing children (Bailey et al. 2000; De Pauw et al. 2011), and it has been theorized that this may lead to higher rates of anxiety (Bellini 2006).

Genetic factors seem to be involved in an individual's propensity towards general "fearfulness," but the environment (e.g., a frightening experience) contributes to the specific fear (Ollendick et al. 2002). However, while most adults attribute a specific phobia to a direct experience of fear conditioning, most children attribute specific phobia to observing a fear response in others, to reading or hearing about a phobia, or to no obvious cause (Ollendick et al. 2002).

Clinical Expression and Pathophysiology

Clinical Features. Individuals with specific phobia experience excessive or unreasonable fear of a

particular object or situation. The fear can occur in the presence of the object or in anticipation of encountering it. When exposed to the phobic object or situation, the individual will almost always experience intense anxiety. In children, this may be expressed by crying, tantrums, or freezing. Individuals with specific phobia often avoid the phobic situation. According to the DSM-IV-TR (American Psychiatric Association 2000), adults must recognize that the fear is excessive or unreasonable, but this may not be true for children. This feature therefore may also not be present in individuals with developmental disabilities such as autism or mental retardation. Several typical manifestations of phobia in children are as follows: Children with a phobia of loud noises may cover their eyes, cry, or have a temper tantrum when exposed to sounds like fireworks, sirens, or thunder, and they may also avoid situations with loud noises, for example, refusing to go to school when they know there will be a fire drill. Children with a phobia of animals or insects often experience fear when exposed to the animal. They may check a room for an insect or refuse to go into a room where the insect had previously been seen. Children may avoid outdoor activities such as going to a park or going camping due to their fear of insects. Other common behaviors include tantrumming or running out of the room when receiving an injection (medical fears), insisting on sleeping with a nightlight on and refusing to walk through the house at night (fear of the dark), or walking up multiple flights of stairs to avoid an elevator (elevator phobia).

Relation to Age. TD children generally follow a natural developmental progression of fears, i.e., fears related to situations, their natural environment, and strangers decrease as they get older, while fears of harm and medical fears increase (Evans et al. 2005). Children with ASD do not seem to follow this same developmental progression; unlike for TD children and children with intellectual disability, mental age does not correlate with fears for children with ASD.

Relation to IQ and Severity of ASD. As with other types of anxiety, rates of specific phobia are higher in children with ASD and average IQ than in those with ASD and intellectual disability.

However, even in children with ASD and below average IQ, rates are still much higher than in the general population. Sukhodolsky et al. (2008) found rates of 31% and 37% in children with ASD with and without intellectual disability, respectively. The majority of studies of anxiety in the ASD population have examined individuals with high-functioning ASD or pervasive developmental disorder—not otherwise specified (PDD-NOS). However, those studies that have compared rates of specific phobia in autism and autism spectrum conditions (e.g., PDD-NOS) have found that rates of specific phobia are much higher in PDD-NOS (e.g., Muris et al. 1998). Nonetheless, given that much research has also illustrated the difficulty with accurately differentiating between autistic disorder and PDD-NOS (e.g., Chawarska et al. 2007; Lord et al. 2000), it is unclear how to interpret these findings.

Relation to Other Problems. In children with ASD, specific phobia is associated with conduct problems, impulsivity, hyperactivity, and somatic complaints. In particular, specific phobia is more related to behavioral problems and other types of anxiety in children with ASD than in TD children (Evans et al. 2005). Children with ASD may be more likely to display challenging behaviors such as tantrums rather than communicate their fears verbally due to their deficits in communication skills.

Pathophysiology. There is little research on the pathophysiology of specific phobia in ASD, but there is emerging research linking anxiety to neurological and genetic abnormalities in individuals with ASD. For example, amygdala volume in children with ASD has been found to be positively correlated with anxiety (Amaral et al. 2008; Juranek et al. 2006), and a particular polymorphism (the 10–10 repeat allele) of the dopamine transporter gene (DAT1) has been associated with greater severity of social anxiety in children with ASD (Gadow et al. 2008).

Evaluation and Differential Diagnosis

Evaluation. Diagnostic markers of specific phobia include an intense and irrational fear of a specific

stimulus or situation, an exaggerated reaction to the feared stimulus (e.g., crying, tantruming, running away), and extreme measures to avoid the feared stimulus. Individuals with specific phobia may also display physical symptoms such as shortness of breath, pounding heart, sweating, nausea, or light-headedness. Individuals with blood or injection phobias may feel dizzy or faint.

In clinical practice, specific phobia is commonly assessed through clinical judgment and parent-report measures, such as the Fear Survey Schedule for Children–Revised (Ollendick 1983), on which parents report how fearful their children are of particular situations and objects. This measure has been used to assess fears of low-functioning children with ASD (Matson and Love 1990).

Research studies often diagnose specific phobia and other anxiety disorders in children with high-functioning ASD using a structured diagnostic interview such as the Anxiety Disorders section of the Diagnostic Interview Schedule for Children (DISC; Shaffer et al. 2000), the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS; Ambrosini 2000), and the Anxiety Disorders Interview Schedule (ADIS; Silverman and Albano 1996). The DISC is usually administered with parents only, while the KSADS and ADIS are administered with both parents and children. The Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I; First et al. 1994) is the adult version of the DISC and has been used with adults with ASD and normal IQ (Hofvander et al. 2009). These standardized interviews assess DSM-IV criteria for anxiety disorders, including the presence of symptoms, the frequency and severity of symptoms, and the extent of functional impairment. Leyfer et al. (2006) created a modified version of the KSADS for use in children and adolescents with ASD, which is called the Autism Comorbidity Interview–Present and Lifetime Version (ACI-PL).

Many research studies also use parent rating scales to examine fears or symptoms of specific phobia in children with ASD. One commonly used parent rating scale is the Child Symptom Inventory (Gadow and Sprafkin 1997), which has slightly different versions for children of

different ages, including the Early Childhood Inventory-4, ages 3–5; Child Symptom Inventory-4, ages 5–12; and the Adolescent Symptom Inventory-4, ages 12–18. However, these checklists measure a number of childhood symptoms and include only one specific phobia item: “Excessive fear to specific objects.”

While some of these measures have not been used with low-functioning children, they may still be appropriate for individuals with cognitive delays. The DISC, the Early Child Inventory and Child Symptoms Inventory, and the Fear Survey for Children (as well as its counterpart, the Fear Survey for Adults) have been used with individuals with mental retardation (Davis et al. 2008). The Fear Survey for Adults has been adapted for adults with mental retardation, and this version demonstrated good internal consistency and correlations with other measures of anxiety (Ramirez and Luckenbill 2007).

Differential Diagnosis. Specific phobia may present similarly to other types of anxiety such as separation anxiety disorder (SAD) or social phobia (SOP) as well as to symptoms associated with ASD such as sensory sensitivities.

Children who have fear of or avoid specific places or situations such as school, extracurricular activities, or playdates may present with similar symptoms as children with SAD or SOP. Children who experience distress around going to school or other places due to separation from their caregivers and/or excessive fear that harm may befall themselves or their caregivers while separated may be more accurately diagnosed with SAD (DSM-IV-TR). However, if children fear or avoid school due to fear of school itself rather than fear of separation, they may meet criteria for school phobia. Likewise, children who avoid school or playdates due to fear of social situations or fear of being judged may be more accurately diagnosed with social phobia.

Specific phobia may also overlap with sensory issues in individuals with ASD. For example, the finding that over 10% of children with ASD have a fear of loud noises (Leyfer et al. 2006) may be due to their sensory sensitivity (Baranek et al. 2006; Ben-Sasson et al. 2007). Reports of fear of objects such as balloons (Muris et al. 1998),

which can make loud, startling noises, may also be related to children’s sensory issues. Individuals with ASD who display fears should be evaluated for sensory sensitivities as well.

Treatment

Behavioral Treatments. Well-established treatments for TD children with fears and phobias usually combine behavioral exposures with a reinforcement system. A core mechanism of the exposure is systematic desensitization (e.g., Wolpe et al. 1973) in which the child is gradually exposed to increasingly anxiety-provoking stimuli. Other specific effective components of these treatments include reinforced practice, participant modeling, contingent reinforcement, prompting, modeling, extinction/blocking, and use of distracting stimuli (Davis and Ollendick 2005; Ollendick and King 1998). No randomized controlled trials or even larger-scale treatment studies have examined the effectiveness of behavioral treatments for specific phobia in children with ASD. However, a number of case studies have used this type of treatment (i.e., gradual exposure with reinforced practice, modeling, and contingent reinforcement) with children with ASD and found it to be effective in reducing their fears (Ellis et al. 2006; Gillis et al. 2009; Love et al. 1990; and Ricciardi et al. 2006). For example, Love et al. (1990) treated a child with a fear of going outside by dividing the front yard into seven distances from the front door and putting a retrievable object (e.g., a sticker or newspaper) in each marked-off section. In this treatment, the parent led the intervention and was coached by the therapist. The parent first modeled walking into the yard, then led the child into the yard, and then prompted the child to go into the yard on his own. The child received praise and a reward (e.g., food or a sticker) contingent upon attempting the exposure. The child was gradually prompted to go further and further into the yard.

Cognitive behavioral therapy (CBT) has been shown to be efficacious in treating anxiety in children with ASD (e.g., Chalfant et al. 2007; Reaven and Hepburn 2003; Reaven et al. 2009;

Sofronoff et al. 2005; Sze and Wood 2007; Wood et al. 2009). The CBT in these studies is similar to CBT used with TD children in that it includes psychoeducation, cognitive restructuring, self-talk, relaxation, and exposure to feared stimuli. However, it has been adapted for children with ASD by simplifying the cognitive aspects and emphasizing concrete aspects such as relaxation and exposure and, in some cases, by addressing poor social and adaptive skills in addition to anxiety (e.g., Wood et al.). While none of these studies examined effects on specific phobia in particular, the CBT used does include similar methods (e.g., graduated exposure, contingent reinforcement) to the behavioral treatments often used to treat specific phobia.

Pharmacological treatments for anxiety have been used off-label with some children and adolescents with ASD, including SSRIs, buspirone, and dextromethorphan. However, these drugs have not yet been tested against a control group or placebo condition in this population (White et al. 2009), and none of these medications have been tested in specific phobia.

Phonemes

Karen Chenausky
Boston University, Boston, MA, USA

Synonyms

[Speech sound](#); [Segment](#)

Definition

A phoneme is a speech sound – the smallest contrastive sound unit in a language. When children learn their native languages, part of what they learn is to correctly perceive, produce, and combine the phonemes of their language. Though most children with autism acquire speech normally, some have difficulties with spoken language. These difficulties can range from “residual speech errors,” which are persistent mispronunciations of one or more phonemes (such as “w” for “r”) past the age of 8, to the complete absence of spoken language.

A phoneme is a cognitive construct, not a feature of the acoustic signal. Acoustically, speech is a continuous signal; however, it is perceived as consisting of a series of distinct phonemes. Though repeated examples of the same phoneme differ slightly from each other acoustically, they are still perceived as belonging to the same phonetic category.

Major classes of phonemes are vowels (such as “a” or “i”), consonants (such as “b” or “s”), and glides (such as “w”) or liquids (such as “l”). Vowels are produced with the vocal tract largely open and unobstructed. On the other hand, consonants are produced with a tight constriction or momentary closure somewhere in the vocal tract. Glides and liquids are produced with an intermediate degree of constriction. Phonemes are classified in terms of phonetic features that describe *place* of articulation (where in the vocal tract the phoneme is produced), *manner* of articulation (how it is produced), and *voicing* (whether the larynx is vibrating during production of the phoneme). For example, “v” is classified as a voiced

labiodental fricative. “Voiced” means that the larynx is vibrating while it is produced. This is in contrast with “f,” which is unvoiced because the larynx does not vibrate during its production. Like “f,” “v” is labiodental; it is produced with a constriction between the lower lip and the upper front teeth. Finally, “v” is a fricative, which means that air passes continuously through the labiodental constriction and causes a white-noise-like sound called frication.

Each language employs a different selection, or *inventory*, of all possible phonemes. Some phonemes, like the “th” sound in English “thin,” are rare across languages. Other phonemes, such as “b,” are used in nearly every language. Phonemes also combine with each other in ways that are determined by each language individually. For example, in Bantu words may begin with the “ng” sound, as in the name of the Ngorongoro Crater. In English, on the other hand, “ng” is only permissible at the ends of words (e.g., “sing”); it never appears word-initially.

It is important not to confuse phonemes with letters. While phonemes can be represented by letters (as we have done in the paragraphs above), the two are not the same. In English, the letter “a” can represent many phonemes, such as the “ey” sound in “apex,” the “ae” sound in “atom,” the “ah” sound in “watt,” or the “uh” sound in “banana.” Also, different letters may represent the same phoneme in different words. For example, the sound “ah” is spelled with the letter “a” in “watt” but with the letter “o” in “stop.” In order to standardize the representation of speech sounds across languages, the International Phonetic Association (IPA) has devised an alphabet in which each phoneme is represented by a unique symbol.

Phonetics

Karen Chenauský
Boston University, Boston, MA, USA

Definition

Phonetics is the study of human vocal sounds, and linguistic phonetics is the study of those sounds

that are used in speech. Some authors use the term “phonetics” to refer only to the study of speech sounds, but the study of nonspeech vocal sounds such as infant cries, coughs, and singing can employ many of the same methods as are used in linguistic phonetics even though speech per se is not involved.

There are many aspects to the study of phonetics, but three main ways of investigating it are by using *perceptual* methods, *acoustic* methods, or *instrumentation*. Perceptual methods involve the auditory analysis of speech or vocal sounds, using either live or recorded stimuli. Since much research concerns the intelligibility, comprehensibility, or other type of impression of the vocal sound on another human, perceptual methods are considered the most ecologically valid. However, the human speech perceptual system is noted for its biases, many gained through experience with speech. These biases help humans filter extraneous information from the speech signal and extract just the information that will be useful for making quick decisions about what is being communicated. However, information which is “extraneous” in this sense is often scientifically useful, so *acoustic* methods are often paired with perceptual ones to provide a fuller picture of the speech signal.

Acoustic research in phonetics incorporates knowledge of normal and disordered vocal tract physiology, mathematical acoustics, signal processing, and perceptual psychophysics. Recordings of vocalizations are digitally processed (generally using an algorithm of the Fourier transform) and displayed on a computer screen in the form of a spectrogram, which is a graph showing the changes in frequency and amplitude of the utterance over time. From this, visual-perceptual analyses can be performed, along with quantitative measurements of frequency and amplitude at various points in the utterance.

Other instrumentation is also used in phonetic research. For example, a palatometer shows where the tongue contacts the hard palate during speech production. A nasometer measures airflow through the nasal passages during speech. X-ray videography and electropalatography give views of how the articulators of speech (lips, tongue, palate, velum, pharynx, and others) move during

utterances. More recently, facial movements involved in speech have been studied using reflective dots and motion-sensitive cameras.

In order to standardize the representation of speech sounds across languages, the International Phonetic Association (IPA) has devised an alphabet used to phonetically transcribe normal and disordered speech.

Phonological Deficits

► Phonological Disorders

Phonological Development

Elizabeth R. Eernisse
Department of Language and Literacy, Cardinal
Stritch University, Milwaukee, WI, USA

Definition

Phonological development refers to the gradual acquisition of an adultlike system of speech

sounds that are used to convey meaning in a language. Phonological development can be considered in terms of both perception and production of speech sounds.

Historical Background

Historically, the development of speech sounds has been characterized in terms of the development of articulation abilities, with recent attention being paid to the notion that a larger set of rules and linguistic representations may also govern how individuals acquire speech sounds.

Current Knowledge

Perception

Research has demonstrated that infants are aware of speech sounds long before they are able to produce them. For example, infants at 1 month of age are able to discriminate speech sound categories such as the difference between phonemes /p/ and /b/ (i.e., categorical perception; Eimas et al. 1971). Over time, infants also develop the ability to track features of speech such as prosody (i.e., changes in pitch and loudness or the “melody” of speech) and stress patterns, as well as realize which distinctions between sounds are not meaningful in their native language (e.g., variability between speakers producing the same sound as in the case of a male versus female speaker, versus the meaningful difference between two distinct speech sounds). In addition, infants as young as 6 months of age have been shown to track the frequency with which speech sounds occur within a speech stream (i.e., phonotactic characteristics) (Saffran et al. 1996), a skill that has been linked to later vocabulary learning. In addition, by 10–12 months, infants demonstrate a reduced ability to recognize nonnative speech sound contrasts as the infant appears to have honed in on the sounds that occur within the language(s) to which he or she has regularly been exposed. It is in this early period that infants typically begin to demonstrate recognition of single words. During the second year of life, infants refine their vocabulary

comprehension abilities to be able to discriminate between words that sound very similar (e.g., “bih” and “dih”) and associate those words to new objects that are encountered in the environment, recognize words when provided with only a portion of the relevant phonetic information, and are able to comprehend words even if they are mispronounced. Perceptual abilities continue to progress as the child begins to associate phonological features with aspects of spoken language (see chapter ► [“Phonology”](#)).

Production

Infants begin to explore and experiment with their vocal tracts from birth. The earliest sounds that are produced are reflexive vocalizations, such as sneezing and breathing. As the infant matures, sounds include cooing and laughter, with increased variety of consonant and vowel-like sounds. Vowel sounds are typically produced the earliest, followed by consonant-like approximations that are produced in the back of the throat (e.g., /g/ and /k/) which are then followed by sounds that are produced in the front of the mouth (e.g., /m/, /n/, /b/, /p/). In addition to adding new sounds to the repertoire, the speech sounds are combined in sequences of increased length and complexity as the infant engages in vocal play. From 6 to 10 months, infants typically produce “reduplicated” syllables (i.e., repeated syllables containing the same consonant and vowel, e.g., “babababa”). From 10 to 14 months, babbling incorporates more variety in terms of sounds/syllables and pitch contours and is referred to as “nonreduplicated.” In addition, at approximately 1 year of age, infants use speech sounds to produce their first spoken words. In typical development, spoken vocabulary continues to grow well into school age and beyond.

As the child acquires more and more words, systematic patterns of sounds often emerge known as phonological processes (see examples of English phonological processes below, Hoff 2005).

- Weak syllable deletion: omission of an unstressed syllable in the target word, e.g., “nana” for “banana.”

- Final consonant deletion: omission of the final consonant in the target word, e.g., “ca” for “cat.”
- Reduplication: production of two identical syllables based on one of the target word syllables, e.g., “baba” for “bottle.”
- Consonant harmony: target word consonant takes on features of another target word consonant, e.g., “guck” for “duck.”
- Consonant cluster reduction: omission of a consonant in a target word cluster, e.g., “top” for “stop.”
- Velar fronting: a sound that is typically produced at the back of the mouth (e.g., /k/ or /g/) is replaced by a sound that is produced further forward, e.g., “ti” for “key.”
- Stopping: a fricative (i.e., a consonant that is produced with friction such as /s/, “sh,” /f/, or /v/) is replaced by a stop consonant in which airflow is completely obstructed (e.g., “ti” for “sea”).

By early school age, most phonological processes have resolved in typical development, as the child’s productions more closely match the adult form. However, some children demonstrate lingering phonological processes that impact intelligibility (see chapter ► [“Phonological Disorders”](#)).

Future Directions

Current research in phonological development is exploring the existence of what would be considered linguistic universals that govern all languages versus the acquisition of language-specific phonological rules.

In addition, a body of research exists that explores phonological development and its impact on the acquisition of reading and writing skills, in hopes of developing targeted instructional techniques for academic success.

Phonological Disorders

Maura Moyle and Steven Long
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

Phonemic errors; Phonological deficits

Short Description or Definition

A phonological disorder is an inability to articulate speech sounds accurately. The disorder may have a motoric (phonetic) component as well as a linguistic or cognitive (phonemic) basis. Therefore, phonological disorders may affect both the

intelligibility of a child's speech and his or her internalized knowledge of the language's sound system. The errors committed are usually rule governed, i.e., they show a pattern across all words spoken.

Categorization

The Diagnostic and Statistical Manual of Mental Disorders Fifth Edition (DSM-5, American Psychiatric Association 2013), specifies four criteria that must be present in order for Speech Sound Disorder (which includes Phonological Disorder) to be diagnosed. First, an individual must exhibit persistent unintelligible speech consisting of phoneme addition, omission, distortion, or substitution, which interferes with verbal communication. Second, the deficits must interfere with social participation, academic performance, and/or occupational performance. Third, the onset of symptoms is in childhood. Fourth, the symptoms cannot be accounted for by another medical or neurological condition.

Epidemiology

Phonological disorders are among the most prevalent communication disabilities diagnosed in preschool and school-age children, affecting 10% of this population. Children with phonological disorders are also at risk for reading and writing disabilities. If left unresolved, phonological disorders have long-term consequences that may interfere with an individual's future social, academic, and vocational well-being, largely resulting from persistent, reduced intelligibility of speech.

For individuals with ASD, impairments of phonological skills may be present, but compared to the difficulties shown in other language domains (social communication, stereotyped lexical usage, etc.), these skills are relatively preserved. Approximately one-third to one-half of individuals with ASD present with significant difficulty using speech as a functional and effective means of communication. In these individuals, it

is not uncommon for vocal attempts to be of limited intelligibility due to difficulties producing a variety of consonant sounds and using more complex syllable structures, such as those in multisyllabic words. The nature of these difficulties is not well documented in the literature; however, underlying difficulties may include challenges with oromotor planning and/or delays in phonological development (Lord and Paul 1997; National Research Council 2001). An estimated one-fourth of children with ASD are non-verbal, i.e., they lack spoken language. Most children with ASD who speak begin to do so by age 7 and almost never after age 13 (Pickett et al. 2009).

Among speaking children with ASD, there is typically no specific developmental impairment at the level of segmental phonology (consonant and vowel production). The speech that they produce will generally be understood, though, as with all children, it will undergo a process of developmental change to become more and more adultlike. Although unintelligible speech is not a core feature, atypical cases have been reported in the literature of children with ASD who exhibit severe phonological difficulties (e.g., Wolk and Giesen 2000). Moreover, there is evidence that distortion errors – which represent a phonetic rather than phonemic disorder – may persist into adulthood (Shriberg et al. 2001). Perception of speech sounds appears to be different in individuals with ASD. Functional imaging studies have indicated that both children and adults with autism show deficits in speech-sound processing (Boddaert et al. 2004). This impairment is limited to speech sounds; it does not affect the perception of tones (Whitehouse and Bishop 2008). The relationship between these deficits and the speech production abilities of individuals with ASD is not yet known.

Natural History, Prognostic Factors, and Outcomes

The development of speech begins at birth. As the speech mechanism systems of breathing, voice, and articulation mature, an infant is able to make a

controlled sound. This begins with soft, repetitive “cooing” vocalizations and by 6–7 months has progressed to repetitive syllables such as “ba, ba, ba” or “da, da, da.” This babbling becomes more elaborated and melodic so that it often has the tone and cadence of adult speech but does not contain real words. By the end of their first year, most children are starting to say a few simple words.

During the second year of life, children slowly develop a single-word vocabulary and by the end of that year most are putting words together. During the period of single-word speech, it is believed that children learn the sound structure of words as wholes. After the point where they have learned around 50 words, they begin to show awareness of the individual sounds or phonemes in words. The errors they commit start to show regularity, so that the same mistakes are committed on the same phonemes in different words (e.g., /s/ will be replaced by /t/ in the words sun, see, sick, etc.).

During the remainder of the preschool years and, for some children, extending into the early school years, there is a gradual process of phonological learning that can be described from two perspectives, one of sound mastery and the other of error suppression. In the first perspective, children are seen to slowly master all the vowels, individual consonants, and consonant sequences of their native language. Certain classes of sounds are mastered earlier than others. For example, many early emerging sounds are made in the front of the mouth by blocking the flow of air or directing it into the nasal cavity: /p, b, t, d, m, n/. Later emerging sounds are either made in the back of the mouth (e.g., /k, g/) or by partially blocking airflow to create fricative sounds (e.g., /s, z, th, sh/). In the second perspective on phonological development, children are observed to show regular ways of simplifying their pronunciations compared to those of adults. These patterns, or phonological processes, include changes to the syllable structure of words (e.g., omitting unstressed syllables or eliminating one of the sounds in a consonant sequence), omissions of sounds (especially at the ends of syllables), and substitutions of earlier/simpler sounds for later/more complex ones (e.g., substituting /t/ for /k/). Many phonological processes occur commonly in

children and are considered to be part of their biological predisposition; these are referred to as “natural” processes. Others may be idiosyncratic or unique to an individual child.

Phonological disorders in children are characterized by speech that is difficult to understand, especially by individuals who do not know the child speaker well. As a rule of thumb, children should be understood by strangers about half the time at age 2, about 75% of the time at age 3, and nearly all the time at age 4. When speech is unintelligible, it is usually due to a combination of common and uncommon errors. Certain of the normal or “natural” phonological processes may persist beyond the ages at which they are normally suppressed. Other atypical or idiosyncratic processes may also be present. There may also be a combination of phonemic (substitution, omission, and addition of sounds) and phonetic (distortions of sounds) errors together in the same child. Individuals with ASD may present unintelligible speech for all these reasons and, in addition, may exhibit disturbances of prosody that further compromise their intelligibility.

Clinical Expression and Pathophysiology

Phonological disorder is an impairment in the ability to comprehend or produce the sound system of a language. This sound system is characterized as having two parts: segmental phonology, which pertains to consonants and vowels and their combination into syllables, and nonsegmental phonology (also called suprasegmental phonology or prosody), which includes speech variables such as rate, stress, intonation, and pause. In the field of speech-language pathology, the term phonological disorder is typically used to refer to segmental problems, specifically difficulty in inducing the rules that govern sound combinations. Thus, a phonological disorder is viewed as a subtype of language disorder (Bauman-Waengler 2012).

With such disorders, errors are observed in the production of individual speech sounds and in the formation of syllable structures of words. Sounds

may be omitted, substituted by other sounds, or added to the normal form of a word. When these errors are numerous or result in sounds quite different from the targets, they may produce speech that is partially to fully unintelligible to a listener, especially one who is unfamiliar with the speaker. Phonological disorders are distinguished from phonetic disorders (also described as articulation disorders) that result from slight misalignments of the articulators during speaking and are manifested as distortion errors. Unlike phonetic disorders, phonological disorders are frequently part of a larger language disorder characterized by impairments of one or more other linguistic domains such as vocabulary, comprehension, morphosyntax, or literacy.

Although nonsegmental phonological or prosodic impairments are normally not considered part of a phonological disorder from a clinical perspective, they clearly belong within the linguistic domain of phonology. Moreover, unusual prosodic features are a concomitant behavior in many individuals with autism. It is one of a number of behavioral red flags that distinguish toddlers with autism from those either developing normally or with other types of developmental delay (McCann and Peppe 2003; Wetherby et al. 2004). Among the speech production behaviors where differences are reported to exist are stress, rate, chunking (verbal phrasing), intonation, and expression of affect. Problems have also been noted in the detection and comprehension of prosodic variation in speech. In spite of this, accounts of prosodic disability in autism are inconsistent and have utilized widely varying populations and methodologies.

Evaluation and Differential Diagnosis

Phonological disorders in young children are assessed through standardized and non-standardized procedures. Optimally, two speech samples are obtained: one of single-word speech, typically elicited through a picture- or object-naming task, and the second of connected speech, gathered through a play interaction or short

interview. To elicit the first type of sample, a large number of standardized, norm-referenced tests of speech-sound production are available for children 3 years or older (e.g., *Clinical Assessment of Articulation and Phonology*, Second Edition, Secord and Donohue, 2013; *Goldman-Fristoe Test of Articulation-Third Edition*, Goldman and Fristoe 2015; *Arizona Articulation Proficiency Scale, Third Edition*, Fudala 2000).

Speech samples of both types are transcribed phonetically and then analyzed to determine whether the child displays primarily speech production deficits (phonetic errors or sound distortions) and/or deficits associated with phonological constraints (phonemic errors of omission, substitution, or addition of sounds). Independent analyses such as a phonetic inventory (listing of all sounds produced, regardless of correctness) are used to evaluate possible sensory or motor limitations. The child is also screened for auditory acuity and is given an oral-peripheral examination to determine whether there exist structural or physiological limitations to speech. Relational analyses such as an assessment of phonological processes (patterns of sound simplification, such as replacing posterior /k, g/ sounds with anterior /t, d/ sounds) are used to determine whether errors are developmentally common or idiosyncratic. The identification of error patterns also forms the basis for treatment to improve speech intelligibility.

Treatment

In the treatment of phonological disorders, the primary goal is to improve a child's speech intelligibility to facilitate effective communication. This entails both teaching the accurate production of speech sounds and improving the conceptual organization of speech-sound information so that phonemic contrasts are clearly marked. Effective and efficient treatment relies on a generalization of learning. The goal is to induce a widespread change in a child's sound system so that it is more in line with the phonology of the target language.

Treatment often occurs in the context of an interdisciplinary service delivery team that may include speech-language pathologists, audiologists, nurses and physicians, occupational and physical therapists, parents, psychologists, social workers, special educators, and teachers. The composition of this team is dependent on the child's needs not only in the area of communication but in development generally. The team initiates and coordinates the optimal intervention program for the child and facilitates the program's transfer and utility in daily settings.

After assessing the phonological disorder and identifying and prioritizing the errors that exist, a treatment plan is developed to correct speech-sound production. The goal of treatment is to improve accuracy and use of speech sounds so that intelligibility is improved in both single words and connected speech. Generalization is sought across all settings in which children communicate. No single treatment approach is used. In general, all approaches utilize structured sound production practice at gradually increasing levels of difficulty.

Intervention for individuals with ASD must often be adapted to suit their unique interests, styles of interaction, and sensory preferences and aversions. For example, the commonly used technique of saturating the child with auditory models of a target speech sound might prove disastrous with an individual who is auditorily hypersensitive. Another common technique, contrasting minimal word pairs such as "call" and "tall," may be difficult to implement because it relies on role reversal, the teacher playing the student, and vice versa.

Phonology

Elizabeth R. Eernisse

Department of Language and Literacy, Cardinal Stritch University, Milwaukee, WI, USA

Synonyms

Articulation; Speech

Definition

Phonology refers to the system of speech sounds within a particular language. Phonology differs from articulation in that phonology is concerned with the rule-governed ways in which speech sounds are used and interact with each other to encode meaning within a language, while articulation is generally associated with the movement of structures to produce speech sounds.

Phrase Length

Joshua J. Diehl
Autism Services, LOGAN Community
Resources, Inc., South Bend, IN, USA
Department of Psychology, University of Notre
Dame, Notre Dame, IN, USA

Definition

Phrase length is a measure of the complexity of expressive language. A phrase is a grammatical construction (e.g., noun phrase, verb phrase) that does not contain both a subject and a predicate; therefore, it does not qualify as a full sentence. It is one type of measure that can be used to estimate an individual's level of spoken language.

Phrenology

Joshua J. Diehl
Autism Services, LOGAN Community
Resources, Inc., South Bend, IN, USA
Department of Psychology, University of Notre
Dame, Notre Dame, IN, USA

Synonyms

[Craniognomy](#); [Craniology](#); [Cranioscopy](#)

Definition

Phrenology was an early psychological theory that mental abilities were compartmentalized in

specific areas in the brain and that the strength of these abilities could be determined by the size of the bump in the skull for that particular ability. Phrenology was originally proposed by Francis Gall in 1796 and was one of the first to suggest that a brain function could be localized to a specific area of the brain. Phrenologists would palpate the exterior skull and, based on this procedure, would generate predictions and psychological analyses of an individual's strengths and weaknesses. This procedure depends on the inaccurate assumption that the exterior surface of the bony scalp is a faithful reflection of the configuration of soft internal brain tissue. This theory received little research support and is typically only mentioned as a historical prologue to modern psychology.

Physical and Neurological Examination

Susan M. Strahosky
School of Medicine and Dentistry, University of
Rochester, Rochester, NY, USA

Definition

The physical examination is performed by a physician, nurse practitioner, or other trained medical care provider to determine the state of health of an individual. It is important for a physical examination to be performed as part of an initial evaluation of a child with an autism spectrum disorder to identify co-occurring medical or etiologic disorders. A standard approach to the assessment of all organ systems is used. The neurological examination determines if abnormalities exist in the central or peripheral nervous system using a standard

approach based on the understanding of motor, sensory, coordination, and cognitive systems.

Historical Background

Kanner's original 1943 case reports of children with autism contain few references to the physical or neurological exam. One child was described as resembling his father physically. Several had an "intelligent physiognomy." There was one child with a supernumerary nipple, but no other congenital anomalies are reported. Physically they were described as essentially normal though 5 of the 11 had an increased head circumference. Gross motor clumsiness was also present in several cases. As the diagnosis was more widely evaluated, initially more focus was placed on a psychoanalytic approach to understanding autism. When interest in exploring the biological basis for autism increased, physical findings were still minimally noted. A review of the literature in 1973 indicated physical findings that were primarily soft signs including poor tone, poor coordination, clumsiness, exaggerated reflexes, and strabismus (Ornitz 1973). Maurer and Damasio in 1983 explored the neurological basis for autism relating core behaviors to known diagnoses and their anatomic correlate to localize areas of dysfunction and better understand the etiology of autism. As autism became understood as a neurobiological disorder, there was interest in the role known congenital medical disorders played in autism. Cases associated with a known syndrome or medical disorder were reported at 10–20% (Barton and Volkmar 1998). However, that number is decreasing as fewer children identified with ASD have a coexisting intellectual disability and intellectual disability is associated with a higher rate of identifiable disorders. A distinction is made between syndromic autism and idiopathic autism with an essentially normal exam (Johnson and Mayes 2007).

Current Knowledge

The complete evaluation of a child suspected of having an autism spectrum disorder is a multipart

process. The physical and neurological exam is informed by a comprehensive medical and developmental history. While performing a detailed physical, dysmorphicologic, and neurological exam is important, the clinical history increases the clinician's index of suspicion. It prompts evaluation of associated findings while performing the exam.

History of delays in reaching multiple developmental milestones can suggest intellectual disability which is a comorbid diagnosis with autism spectrum disorder in some 50% of children. The physical exam can provide findings suggestive of a genetic disorder associated with intellectual disability. History can indicate symptoms of disorders that are increased in children with autism. These include sleep disorders and gastrointestinal problems. Oral findings, body habitus, and growth should be assessed as contributors to these problems.

The history of functional abilities will characterize eating, sleeping, toileting, and other activities of daily living such as dressing. Performance of these tasks can help characterize motor findings associated with autism. Motor clumsiness or dyspraxias (motor planning problems) will present as difficulties learning to chew or drink from a cup or, in the older child, delays in learning to dress or to write. Sensory integration difficulties can present as issues with food textures, temperature, and taste. Tactile sensitivity to clothing tags or tight clothes can complicate getting dressed. The clinician will want to evaluate tone and coordination and motor function to better characterize these presenting concerns.

Family history will indicate others with autism, intellectual disability, genetic disorders, or birth defects. Preconception events such as advanced parental age as well as preterm birth complications may raise the risk for ASD. The exam can identify findings that are familial or complications of prematurity such as chronic lung disease, visual impairment, or growth problems. Prenatal exposures can have effects that are identifiable on exam such as microcephaly and facial findings seen with fetal alcohol syndrome.

Parents who are bringing a child either for further evaluation following diagnosis or with

significant behavioral concerns prior to diagnosis may wish to review resources detailing how to approach the exam and prepare the child. This will engender less stress on the child's part and assist the clinician in having time for observation and examination. Children can be prepared visually with videos, social stories, books, or pictures. Doctor kit toys can allow the child to practice the exam. Office staff appreciate a parent letting them know what to expect from the patient. For example, a child who is distressed with noise and movement may be brought in as soon as possible to wait in a quiet room instead of a busy waiting room. Staff may suggest other appointment times that will facilitate this. Vital signs may need to be done by hand rather than machine. In making the appointment, staff can let parents know how much time will be needed and what information they should make available. If the clinician has time to review school reports or testing results before the visit, additional adjustments can be made knowing the child's level of function.

It is not unusual for children with disabilities to have difficulty with office-based screenings of hearing and vision. The child may not be able to follow the directions due to cognitive, verbal, or attention problems, but it may be assumed that the child did "not want to cooperate." A normal newborn hearing screening test does not rule out a progressive hearing loss. Staff will want to tell the examiner about the interaction as well as the results and see that a reliable result is obtained or a referral made to an audiologist where a variety of evaluations are available. There is an increase in hearing and visual impairment in autism spectrum disorders. Autism spectrum disorders are more frequent in children with optic nerve hypoplasia such as septo-optic dysplasia.

Interaction during the physical examination provides opportunities for additional informal observation of core behaviors diagnostic of an autism spectrum disorder including deficits in social interaction and communication and repetitive behavior. A young autistic child may be indifferent to the examiner. Other young children may appreciate the chance to play with the "doctor's toys," and this can be a measure of engagement, enjoyment, and turn taking. Response to the

examiner's directions allows observation of eye contact and engagement with the examiner and the ability to imitate. For the verbal child, vocal quality, tone and prosody, and the ability to follow verbal directions as well as the patient's comments and questions can be assessed. Equally important are associated behavioral findings that include pica, self-injury, irritability, ADHD-type symptoms, anxiety, or depression. The physical exam offers opportunities to observe activity level and impulsivity related to ADHD. A child who can talk but will not can be assessed for autism but also for selective mutism, social anxiety, or depression.

Physical evaluation for a child with a suspected autism spectrum disorder includes a comprehensive pediatric assessment. Vital signs and growth parameters should be reviewed. Symmetric growth delays can be familial or indications of a genetic syndrome. Overgrowth can also suggest a genetic contribution (e.g., Sotos syndrome). A short child with a preserved head circumference may have a genetic or endocrine disorder.

Measurement of head circumference is important. Macrocephaly is seen in 25–30% of children with autism. Microcephaly is present in 5–15% and is associated with a poorer outcome. If microcephaly is present at birth, this can indicate prenatal or genetic problems. A normal head circumference at birth followed by poor growth may be due to perinatal event. In Rett syndrome, head growth decelerates in the second half of the first year of life.

Head circumference is normal or below average in autism spectrum disorders at birth followed, in some children, by a rapid increase in growth leading to macrocephaly as a toddler. This does not persist into adulthood being present in 1–3% of adults with ASD (Myers 2009). Macrocephaly is associated with PTEN along with associated skin findings of lipoma and penile freckling.

Examination should look for comorbid medical conditions. These include, for example, evaluation of middle ear status where infection or fluid can lead to conductive hearing loss. A small mid-face, high arched palate, or enlarged tonsils with a history of sleep disturbance suggests a risk of obstructive sleep apnea. A child with GI

complaints may have abdominal fullness, discomfort, or a palpable mass in the left lower quadrant consistent with constipation. Obesity can complicate the presentation for a child with hypotonia and/or motor delays. The presentation of some disorders changes over time and repeated exams can be informative. Head growth trends can be confirmed, and findings may become more typical of a particular syndrome.

A careful dysmorphism examination is indicated. In general, dysmorphic features and a lower IQ increase the likelihood of finding a medical biologic diagnosis.

Examination of the head includes (in addition to head circumference) examination of head shape and hair whorl patterns. Facial proportion evaluation can identify prominent forehead, frontal bossing, small midface, or chin. Ear placement, size, and structure should be noted, as well as the presence of tags or pits. Eye exam includes eyebrow, eyelids, shape, position, and patterns and pigmentation of the iris. Examination continues with the shape of the nose and formation of the philtrum. Size of the mouth, shape of lips, and position (upturned or downturned lips) should be noted. Oral exam includes tooth shape and enamel defects, shape of hard palate and uvula, and the tongue.

Examination of the hands and feet is also informative. Hand exam includes finger length and relative proportion, separation or syndactyly, clinodactyly, and palmar creases. Significant second and third toe syndactyly is a finding in Smith–Lemli–Opitz syndrome which is associated with autism spectrum disorder. Other findings include ptosis, cleft palate, and microcephaly and growth retardation (Smith’s 2006).

Detailed skin exam with an ultraviolet Wood’s lamp looks for findings such as café au lait spots or axillary freckling characteristic of neurofibromatosis or shagreen patch and pale areas/ash leaf spots characteristic of tuberous sclerosis (Smith’s 2006). Lipomas and penile freckling are associated with PTEN.

Known genetic syndromes include chromosomal and single gene disorders. Down syndrome is a chromosomal disorder (trisomy 21) that is associated with a characteristic pattern of findings. Up to 7% of individuals with Down

syndrome are identified as having an autism spectrum disorder. Findings on exam can include microcephaly, flattened occiput, small ears, epicanthal folds and speckled iris, short neck, single palmar crease, and hypotonia.

Fragile X is a single gene disorder (*FMR1* gene) found in 1–3% of children with an autism spectrum disorder. Physical findings include macrocephaly, prominent ears, hypotonia, and macroorchidism identifiable after puberty.

The neurological exam typically includes assessment of cranial nerves, muscle strength and tone, reflexes, and gait. In assessing children on the autism spectrum, hand, finger, and gait stereotypies are often observed. Additional observation may be necessary to discriminate tics from stereotypy. Differences can be seen qualitatively in the performance of skills.

Details of the exam change with the age of the child. In the infant, this will include an assessment of the primitive reflexes and whether they are abnormally persistent. Focal findings and asymmetries of tone leading to delays raise concerns for intracranial processes. In an evaluation of children age 2–6 with an autism spectrum disorder and no diagnosable medical condition, over 60% had hypotonia and/or hyporeflexia (Akshoomoff et al. 2007). Hypotonia with regression and FTT may raise suspicion of a mitochondrial disorder. Assessment of functional abilities provides additional information about delays, regression, or disordered patterns of development. Unusual gait patterns have been associated with autism spectrum disorders, though not all researchers have found differences (Ozonoff et al. 2008). Persistence of primitive reflexes, regression, or asymmetry of motor findings may appear with repeated exams.

In older children, additional assessment of neurological soft signs will help characterize motor deficits or delays. These include assessments such as posturing or motor overflow when performing stressed gaits, motor impersistence or tremor, synkinesis, and motor movement. A drawing with the child’s name offers information about motor and cognitive skills. Additional assessment of verbal and nonverbal language enriches this evaluation.

Future Directions

As noted, autism without a known medical or syndromic diagnosis, referred to as idiopathic autism, is less likely to be associated with intellectual disability (Johnson and Mayes 2007). However, an increased number of dysmorphic findings have been identified in individuals with idiopathic autism (Ozgen et al. 2011). Use of a systematic dysmorphology examination may eventually identify phenotypes that can be correlated with newer genetic information. Currently, microarray analysis can identify genetic differences in up to 10% of cases of idiopathic autism (Miles 2011).

There are also consistent reports of motor delays and deficits in gait and praxis reported in the children with nonsyndromic autism that distinguish them from nonautistic peers (Fournier et al. 2010). It is hoped that a more systematic evaluation of these findings and their course over time can also identify diagnostic subgroups that will correlate with outcome.

Physical Therapy

Beth Garrison
Hartford Hospital Pain Treatment Center, Bristol,
CT, USA

Synonyms

Physical medicine; Physiotherapy; PT;
Rehabilitation

Definition

Physical therapy involves the treatment and prevention of physical disorders or injuries that cause a person to lose normal mobility, strength, range of motion, or quality of their physical functioning. Physical disorders can be due to medical problems related to congenital conditions, acquired diseases and illnesses, or the result of an individual's inadequate maintenance of proper posture and joint alignment over time.

Physical therapy is performed and overseen by a licensed physical therapist, also known as a

PT. Physical therapists are trained healthcare providers who evaluate, diagnose, and treat people of all ages, from newborns to the oldest individuals. PTs use a patients' history, medical records, and a full physical examination to determine a plan of care that involves education, treatment, and maintenance of any gains achieved. PTs are also involved with the training and education of a patients' caregivers, including parents, spouses, teachers, aides, and other individuals.

Physical therapy can utilize many treatment modalities such as specific exercises, manual treatments, gait and movement retraining, manipulations of tissue and/or joints, education, and other interventions. Treatments can also be performed by physical therapy assistants who act under the direction of the physical therapist.

Because autism is a pervasive developmental disorder, it is common for people with autism to have delays, differences, and disorders of their gross motor skills which can benefit from physical therapy intervention. In very young children, physical therapy can improve basic motor skills like sitting, rolling, standing, and playing. PTs can provide education to parents for techniques they can use to help the child gain strength, coordination, and improved movement skills.

As the child grows older, the PT intervention usually shifts to a school-based program that focuses on more advanced skills such as running, throwing, catching, and climbing. These physical skills can facilitate participation in recess, play, and sports which in turn can improve the child's social engagement with other children. These treatments can be performed one-on-one or in typical school activities. Frequently, physical therapists will pull in non-autistic kids to work in group settings so that the social aspects of the child's physical skills are also developed. The educational training from the PT in the school focuses on tools that help the staff further build the child's social/physical skills.

Physiological Measures of Parental Stress

Reina S. Factor, Deanna M. Swain and
Angela Scarpa
Virginia Polytechnic Institute and State
University, Blacksburg, VA, USA
Virginia Tech Autism Clinic and Center for
Autism Research, Blacksburg, VA, USA

Synonyms

Heart rate variability (HRV); Respiratory sinus arrhythmia (RSA); Stress reactivity

Definition

Caregivers of children with Autism Spectrum Disorder (ASD) experience greater levels of parenting stress than parents of typically developing (TD) children (Davis and Carter 2008; Estes et al. 2013). Although self-reported stress measures are informative, physiological measures of stress provide a more objective method for studying individual differences and underlying biological influences in stress reactivity. High-frequency heart rate variability (HRV) is the variation in interval between heartbeats and is parasympathetically mediated, whereas heart rate measures the number of times the heart beats per min and includes both sympathetic and parasympathetic influences. Higher child ASD traits have been positively related to greater HRV increase or change in mothers during a stressful interaction (Factor et al. 2017). In the same study, maternal self-report of stress and HRV were not significantly related, which suggests that physiological and self-report measures of stress may tap into different components of stressful experiences (e.g., trait versus state, context specific). Research suggests that the measurements of baseline HRV and HRV reactivity likely capture various regulatory abilities. HRV reactivity provides an estimate of the degree of adaptability in certain contexts, whereas baseline

HRV suggests the capacity to change or engage in regulatory strategies.

Since HRV has been used to indicate emotional responding and flexibility, as well as psychopathological features and processes (Thayer and Lane 2000), there are different possible interpretations for the finding of increased HRV in mothers. If context is not considered, higher baseline HRV may reflect a greater capacity for regulated emotional responses, such that parents whose children have more severe ASD traits might have developed more adaptive coping mechanisms. However, previous research has suggested the importance of considering HRV reactivity in the context of the situation. Hastings et al. (2008) indicated that Respiratory Sinus Arrhythmia (RSA), another index of HRV, changes depending on the situation and demonstrated findings that showed lower RSA in threatening situations might reflect the use of effective coping strategies, whereas increased RSA in nonthreatening situations might reflect more adaptive responding. With this in mind, the increase in HRV during the parent-child stressor actually may reflect an atypical coping response during a stressful situation in parents with children with ASD traits.

Preliminary findings also support the hypothesis that RSA reactivity moderates the relationship between maternal rigidity (Condy, Factor, Swain, Strege, Scarpa, in press), often associated with the Broad Autism Phenotype (BAP), and maternal affect during a challenging interaction between mother and child. BAP rigidity and RSA reactivity predicted maternal affect above and beyond the powerful effect of child social impairment. While these findings are preliminary, the results support further investigation of the role of physiological responding in this population in a larger sample. Results also likely suggest that parents with RSA augmentation and higher inflexibility may be less able to physiologically mobilize resources during a stressful task to engage positively with their children.

Overall, further exploration of treatments that target autonomic flexibility is needed in the field, as it may serve as a mechanism for change in parent and child behavior. This would be a rich area of further exploration as there appear to be

differences in physiological presentations of parents of children with ASD compared to those of TD children.

Piagetian Stages

Suzanne Macari

Yale Child Study Center, New Haven, CT, USA

Definition

Jean Piaget advanced the idea that the growth and development of cognitive skills from infancy through adolescence undergoes a series of defined stages that begin with reflexes and eventually develop into the ability to engage in formal logical thinking about abstract concepts. He described four major stages of development: (1) sensorimotor, (2) preoperational, (3) concrete operations, and (4) formal operations.

Historical Background

Arguably the most influential figure in the field of developmental psychology, Jean Piaget authored seminal work on the development of children's intelligence. He posited that cognitive and intellectual changes are the result of development, an active process that the child brings about through interactions with her environment. This process encompasses a series of successive qualitative changes of cognitive structures or schemata created by the child through experience. Piaget's background as a biologist shaped his thinking about the process as a continuous exchange between the individual and the physical world; in other words, “intelligence finds itself entangled in a network of relations between the organism and the environment” (Piaget 1952, p. 19). Piaget's body of work emerged based on extensive, meticulously detailed documentation of his own three children's behavior from birth through adolescence (Piaget 1951, 1952).

The Sensorimotor Stage (Birth to 2 Years)

Piaget (1952) described four stages of cognitive development, the first of which is sensorimotor development. This is the period from birth to approximately 24 months of age that begins with a few reflexes and ends with the appearance of language and symbolic representation of the world. Knowledge in this stage can only be derived from interactions with the physical world, and development proceeds from this exploration. Infants' sensorimotor intelligence proceeds through six increasingly complex stages, each one building on the achievements of the last. In this stage, infants and toddlers do not yet possess the full power of symbolic representation, or language, so must rely on their direct experiences with objects. By around age 2, the child's capacity to represent action in the mind increases, allowing for conceptual thought, thus lessening the dependence on physical and sensory experience.

Substage I: The Use of Reflexes (0–1 Month)

Infants are born with several reflexes, or general action patterns, such as sucking, grasping, and looking. Each reflex constitutes an "organized totality" that includes perceptions, coordinated movements, and a need; it is more than just a "summation of movements" (Piaget 1952, p. 38). These reflexes differ from simple reflexes (i.e., blinking) in that they are modified with experience. At first there is no differentiation among stimuli; for example, newborn infants will suck on a blanket and on a nipple with equal vigor. After several weeks, the infants adjust their sucking to the specific object in their mouth.

Substage II: Primary Circular Reactions (1–4 Months)

When action schemes incorporate new objects, infants move into the second substage of sensorimotor development. In this period, reflexes expand into larger coordinated behaviors, primarily centered on the infants' own bodies. Piaget described systematic thumb sucking and tongue protrusion, looking, hearing and phonation, and prehension in this substage. Out of the single behaviors of grasping objects and sucking objects

grows the integration of these two actions: grasping an object and bringing it to the mouth to suck. The ability to thumb suck at will is one of the *first acquired adaptations* that develops during this period. Turning to find the source of a voice is another primary circular reaction, reflecting coordination between hearing and vision. The term *primary circular reactions* refer to such behaviors. Reactions are primary because they focus on the infants' own bodies, and they are circular because they form "cycles of movements that repeat an interesting sensation discovered by chance" (Muller 2009, p. 208).

Substage III: Secondary Circular Reactions, or the Procedures Destined to Make Interesting Sights Last (4–8 Months)

One of the notable changes in this period is that the child's behavior becomes increasingly oriented toward the environment, beyond her own body, including people, animals, objects, and events. At this time, infants begin to reproduce interesting actions, such as banging, shaking, and waving, especially when these actions cause an interesting visual effect or sound. "Everything thus goes back to movements of legs or feet, arms or hands, and it is these 'circular' movements of prehension which become differentiated in movements directed at shaking, swinging, displacing, rubbing, etc." (Piaget 1952, p. 178). Infants begin to understand that the interesting events are related to their physical activity and thus reproduce the actions. Another characteristic of this period is the shift toward intentional, goal-directed behavior. During this period, infants still lack the concept of object permanence (see section "Substage IV").

Substage IV: Coordination of Secondary Schemata (8–12 Months)

Infants begin to use means to attain ends that are not attainable directly. For example, they will push aside a pillow to reach a toy, or pull a string to obtain an object attached to one end. The main achievement of this period is *object permanence*, the awareness that objects exist when they are no longer in sight. During this period, infants begin to search for objects that disappear, indicating that

they understand that objects still exist after they disappear from view. The fragility of this mental representation, however, is exemplified in the *A-not-B error*. Once infants have searched for a hidden object at one location (A), when the location is moved (B) they continue to search for it at location A. Not until around the first birthday is the infant able to inhibit search at the previous location and look for the object at the new location.

Substage V: Tertiary Circular Reactions, or the Discovery of New Means Through Active Experimentation (12–18 Months)

Beginning at 12 months of age, infants begin to explore their worlds more actively, “experimenting” with objects, intent on seeing how they behave in new situations. Once making such discoveries, they are repeated, but these *tertiary circular reactions* differ from the previous kinds in that the infant varies the actions slightly each time. In this stage, rather than applying the same schemata to problems, they now find new means through trial and error. In contrast to secondary circular reactions, in which infants attempt to recreate a certain event, tertiary circular reactions aim to “ferret out new phenomena” (Piaget 1952, p. 274) in the process.

Substage VI: Invention of New Means Through Mental Combinations (18–24 Months)

In this final stage, the child begins to invent as well as discover. Rather than relying on trial-and-error experimentation, the child begins to be able to devise solutions to simple problems through representation (thinking), independent of immediate experience. In effect, the experimentation happens in thought. This development of mental representation fosters another hallmark of this period, *deferred imitation*, whereby children form mental representations of events so enduring that they can repeat others’ behaviors hours or even days after it was first observed.

The Preoperational Stage (Ages 2–7)

During the preoperational stage, the child becomes progressively more able to internally represent events. One manifestation of this is

symbolic play. In such play, a child might take a piece of bread and play with it as if it were an airplane. Often, but not always, these symbols resemble their targets visually. Piaget recognized the value of symbolic play as “. . .the creation of symbols at will in order to express everything in the child’s life experience that cannot be formulated and assimilated by means of language alone” (Piaget and Inhelder 1969, p. 61). Spoken language, itself symbolic, begins to develop more fully during this stage, from one-word utterances to two-word phrases followed by short sentences and finally a gradual acquisition of grammatical structures. Children’s drawings during this period progress from scribbles to realistic representations of objects.

Piaget described two specific limitations to children’s cognitive development in this phase, *egocentrism* and *centration*. Preschool children still possess notable *egocentrism*, or the perception of the world strictly from one’s own point of view. Illustrating this concept is Piaget’s three mountains task (Piaget and Inhelder 1969), wherein 4-year-olds sat at a table in front of a model of three mountains while a doll was placed in a chair across them. The children were shown photographs of the model from different angles and were asked which one the doll would see, for which most children chose the picture depicting the scene as it looked to them. The ability to take another’s perspective does not emerge in most children until the age of 6. Egocentric communication and thinking is also prominent at these ages. In *centration*, children focus on a perceptually salient dimension of a problem at the expense of other less salient but equally important dimensions. For example, Piaget presented children with two trains running on parallel tracks in the same direction, but one ahead of the other. When they stopped, Piaget asked which train traveled for the longer time/the longer distance/at the faster speed. For all three questions, most of the 4- and 5-year-olds answered that the train that was farther ahead on the track was the one that traveled longer/farther/faster, regardless of the actual duration, length, or speed of the journey. Not until several years later do children consider multiple dimensions of a problem.

The Concrete Operations Stage (Ages 7–12)

It is not until about age 7 that children begin to reason logically about physical phenomena. Typifying the abilities of this stage of development is the concept of *conservation*. The basic premise of this concept is that changing the appearance of objects does not change their key properties, such as amount or material. Below the age of 7, children typically cannot hold one dimension constant while it changes in another dimension. Problems of this kind are tested in three phases. First, for example, the child is shown two rows of eight coins parallel to each other, and then watches while one row is stretched out. In the third phase, she is asked if the number of items is the same or different. Before the concrete operations stage, the child will typically say that this longer row now contains more coins, although she observed the process and saw that no new coins were added. By centering on the perceptual feature of length and ignoring the transformation, she mistakenly believes that one row contains more coins. In addition to the conservation of number, there exists conservation of liquid quantity, conservation of area and mass, and conservation of volume. Understanding such transformations in all of these situations is mastered in the concrete operations stage. As the name suggests, however, understanding is limited to concrete situations, and does not extend to more abstract or hypothetical situations. Through the development of logic, advances are made during this period in the development of seriation and categorization, forming the basis for number concepts, as well as the development of moral concepts such as laws, rules, lying, intentions, and justice.

The Formal Operations Stage (Age 12 and Beyond)

Formal operational thinking involves the development of abstract reasoning and logic to solve a variety of problems. Unlike the other three stages, Piaget believed that formal operations are not universal; not all adolescents fully attain the capabilities of this stage. While concrete thought is limited to tangible concrete problems of the present, formal operations involve propositions, hypothetical problems, or problems in the future.

During this stage children can also become aware of their own feelings and thoughts; in other words, they become capable of introspection. Formal thought has three types of structures: hypothetical-deductive reasoning, scientific-inductive reasoning, and reflective abstraction.

Hypothetical-deductive reasoning involves reasoning from premises which are hypotheses rather than verified facts. Problems of this sort are exemplified by questions like the following: “The car is smaller than the SUV and the SUV is smaller than the truck. Is the car smaller than the truck?” The child who can work this out in her head as opposed to needing objects or drawings to illustrate the problem is using deductive reasoning. One can also reason about hypotheses based on false premises and still come to a logical conclusion.

Scientific-inductive reasoning is reasoning from specific facts to general conclusions, much as scientists do. At this stage, children are capable of forming hypotheses, experimenting, controlling variables, and drawing conclusions in a systematic fashion. One feature of scientific reasoning is the ability to think about several different variables at the same time; another feature is the ability to reason systematically about all possible outcomes of a situation. The pendulum problem requires such reasoning. Children are presented with a pendulum consisting of a weight at the end of a string, set in motion. They are then provided with strings of varying lengths and different weights, and are asked to determine what controls the pendulum’s rate of movement. Children often consider important the length of the string, the weight at the end of the string, the force in setting the pendulum in motion, and the height from which the weight is dropped. The rate of oscillation, however, is controlled solely by the length of the string. The task is to isolate this factor and be able to exclude the others. Children at the level of formal operations work through this in a systematic fashion, exploring all possibilities and finally determining that a single factor influences the rate of motion.

Reflective abstraction is the key mechanism of the construction of new knowledge. Through internal thought or reflection, one can generate

novel information, particularly logical relationships. Understanding of analogies is a prototypical example of this mechanism as it requires construction of relationships between members that comprise the analogy (Wadsworth 1984, p. 146). What is needed for complete mastery of analogical reasoning is not only which members fit together (this could be solved in an associative manner) but also why they do and the awareness of the relationship between two pairs of items. Reasoning about such a relationship goes beyond what is observable, an ability that does not arise until this stage of development.

Current Knowledge

Piagetian Stages and Autism

(Note: For a review of research on the sensorimotor stage in autism, please see the entry ► [“Sensorimotor Development”](#)).

Preoperational

Of all the skills described in Piaget’s body of work, the one perhaps most heavily studied in children with autism has been symbolic play. Wing and Gould (1979) early large-scale study of children with suspected autism even characterized the syndrome by deficits in imagination in addition to the core features of impaired communication and social interaction. Impairments in pretend play have been noted in children with autism of various ages (Bartak et al. 1975; Demyer et al. 1967; Doherty and Rosenfeld 1984) and also when compared to developmentally matched (Rutherford and Rogers 2003; Sigman and Ungerer 1984; Stone et al. 1990; Wing et al. 1977) or language-matched (Baron-Cohen 1987; Charman et al. 1997; Jarrold et al. 1996; Libby et al. 1998; Riguet et al. 1981) controls using a variety of metrics of pretend play. The few studies that have reported no imaginative play deficits may have done so due to floor effects in the comparison groups (e.g., Lewis and Boucher 1988). Another preoperational skill, visual perspective-taking does not seem to be impaired in children with autism (Hobson 1984; Reed and Peterson 1990; Tan and Harris 1991; but

see Yirmiya et al. 1994) or adolescents with Asperger syndrome (David et al. 2009).

Concrete Operations

Relatively few studies have been conducted on conservation and seriation skills; adolescents and adults with autism and intellectual impairment were found to perform at the same level or better than intellectually impaired controls but worse than mental-age-matched typically developing children (Yirmiya and Shulman 1996). In contrast, categorization abilities of children with autism have garnered much interest in recent years. Results of these studies have been mixed, depending on the type of categorization task employed. Generally, children with autism do not appear to be impaired in categorization tasks that are relatively simple, that is, using relatively simple sorting principles such as color, size, or shape (Sigman and Ungerer 1984; Tager-Flusberg 1985). As tasks become more complex and involve more atypical exemplars, for example, categorizing a groomed French poodle among other dogs, individuals with autism show impairments in terms of accuracy or reaction time (Gastgeb et al. 2006; Klinger and Dawson 1995; Shulman et al. 1995).

Formal Operations

Analogical reasoning has been studied in high-functioning children and adolescents with autism, and was found to be intact both for picture analogies (Morsanyi and Holyoak 2009; Scott and Baron-Cohen 1996) and scene analogies with thematic content (Morsanyi and Holyoak 2009). Furthermore, no group differences were observed in a task of inferential transitive reasoning (Scott and Baron-Cohen 1996). A number of studies, however, have reported deficits in conceptual reasoning in high-functioning adolescents and adults with autism as measured by various standardized tests (e.g., the Verbal Reasoning domain of the Stanford-Binet; Carpentieri and Morgan 1994; Minshew et al. 1997).

²Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Synonyms

[Feeding disorder](#); [Scavenging](#)

Short Description or Definition

Pica is an eating disorder narrowly defined as the ingestion of nonfood items or nonnutritive items (e.g., clay, hair, paint chips, paperclips, coins)

which has been present for at least 1 month. The word “pica” comes from the Latin word for the magpie bird (*Pica pica*) known for eating anything. Currently, pica is included as one of three subtypes under Feeding and Eating Disorders of Infancy and Early Childhood in DSM-IV-TR (APA, 2000). A broader definition of pica has been used in the literature to include the eating of food from inappropriate places (e.g., out of the trash can, off floor). While it is developmentally appropriate for children under the age of 24 months to mouth and potentially swallow non-edible objects, it is considered pathological when this behavior persists into older years (Baltrop 1966; Stiegler 2005). Individuals with intellectual disability (ID) and autism spectrum disorders (ASD) often present with comorbid pica that ranges from a mild, occasional behavior to life threatening. In light of the potential serious consequences, screening at minimal and further evaluation and treatment of pica as indicated should be considered in the care of individuals with ASD.

Categorization

Pica items or targets are strikingly diverse and include household products, small toy parts, organic materials, cosmetics, and art supplies. Table 1 lists a variety of pica subtypes that have been identified and specifically named, all ending in “-phagia.” Other pica targets are not formally

Pica, Table 1 Subtypes of pica

Subtype	Target
Acuphagia	Sharp objects
Amylophagia	Laundry starch
Cautopyreiophagia	Burnt matches
Coprophagia	Human or animal feces
Foliophagia	Leaves, grass, acorns, pinecones
Geomelophagia	Raw potatoes
Geophagia	Dirt, clay, sand
Lignophagia	Wood, bark, twigs
Lithophagia	Rocks, gravel, pebbles
Pagophagia	Ice, freezer frost
Plumbophagia	Paint chips
Tobaccophagia	Cigarette butts
Trichophagia	Hair

labeled (e.g., rubber gloves, coins, buttons, insects, pillow stuffing, candles, toiletries) but have been reported in individuals with ID and/or ASD (Stiegler 2005).

Epidemiology

Pica has been found in a wide range of cultural groups across the world (Ali 2001). However, we are unaware of any large-scale studies on the prevalence of pica in the general population. Pica is generally thought to often go unrecognized and underreported (Ali 2001). Prevalence rates reported for pica specifically in individuals with ASD with ID have ranged from 6% to 25%, but samples have included primarily institutionalized samples (Ali 2001; Stiegler 2005). Pica is one of the more commonly found eating disorders in ASD, but future studies are needed to understand the prevalence of pica in ASD, particularly in individuals with ASD but without co-occurring ID.

Natural History, Prognostic Factors, and Outcomes

Pica has been reported throughout the world and, in fact, is an accepted practice in some cultures. Geophagia, the ingestion of dirt, clay, and soil, has specifically been associated with pregnancy in some societies, including regions of Southern United States as well (Ali 2001; Stiegler 2005). Pica has also been observed in the presence of hunger, gastrointestinal distress, and micronutrient deficiencies such as iron and zinc (Young 2010). Conversely, pica may result in micronutrient deficiencies (Ali 2001). There has been limited conjecture that pica is associated with alteration in the dopamine system (Singh et al. 1994).

Gender differences of pica have not been reported in young children, but pica is rare in males *without* ID. Pica becomes more common in those individuals with more severe ID. ASD has been more frequently associated with pica than other developmental differences such as Down syndrome (Kinnell 1985). Little is known about the long-term prognosis and outcome of

pica in ASD. Although long term, improvement management in an institutionalized setting has been reported for individuals with ID (Williams et al. 2009), pica has been noted to be resistant to treatment (Kern et al. 2006).

Clinical Expression and Pathophysiology

Individuals with pica may be very specific about chosen pica targets (i.e., seek out only metal objects) or very indiscriminate (ingesting any nonfood items within their environment). Likewise, the pica behavior may seem to have a compulsive quality whereby individuals spend extraordinary time and effort in searching out pica targets. These individuals may engage in disruptive, aggressive behaviors when pica is thwarted or interrupted (Bogart et al. 1995). This driven nature of pica has led to speculation that pica may be an obsessive-compulsive disorder. In other individuals, the pica behavior may occur in a more random fashion whereby the opportunity presents itself (e.g., cigarette butts are left in an open container). In those with ASD who have high rates of sensory differences, there has been considerable speculation that pica may be a form of seeking sensory input.

Pica is seen in a wide range of children with ASD but is believed to continue into adult hood, at least in individuals with co-occurring severe ID. Individuals in institutional setting are generally believed to present with more pica than other populations. However, as already mentioned in a previous section, our knowledge of the course of pica in ASD specifically is limited by the lack of large-scale, rigorous studies.

Pica presents with a variety of subsequent health risks, including toxicity, obstructions, perforations, and even death (Bell and Stein 1992; McLoughlin 1988; Rapp et al. 2001). Sharp or bulky objects that have been ingested have the potential to cause perforations or blockages of the respiratory or gastrointestinal tracts. Persons who eat paint chips are at risk of lead poisoning. Parasites that live in dirt or clay can cause infections if eaten. Patients who have eaten an irregular amount of a nonfood substance risk malnutrition

and the under- or overconsumption of calories. Dental health is also threatened with repeated chewing hard or abrasive items.

In addition to the health consequences of pica, there are adverse social consequences. This is particularly for individuals who engage in more “unclean” pica such as ingestion of feces, trash, and cigarette butts. Caregivers and peers may be likely to limit their interactions to avoid the unpleasantness associated with the pica behavior.

Evaluation and Differential Diagnosis

Screening and Diagnostic Evaluation

Screening for pica within the context of any evaluation for ASD is well warranted given the high rate of pica in individuals with ASD. This screening may simply be systematic interview questions directed toward parents and other caregivers as part of an evaluation for ASD. Screening questions for pica should also be included in intake assessments for individuals with ASD of all ages. That is, any educational, therapeutic, and other programs for individuals with ASD should screen for pica. If an individual is screened to be positive for pica, a more comprehensive assessment of pica should be pursued. This would first involve interviewing those involved in the care of the individual with ASD regarding observed pica behavior. When possible, an interview with the individual with ASD regarding pica practices should be pursued.

Medical and Nutritional Evaluation

A thorough medical history and evaluation should be conducted when pica is present. Medical testing to rule out the presence of parasites, rule out leading poisoning or other toxins, and to rule out nutritional deficits such as iron and zinc deficiencies should be considered. Additional nutritional testing may be justified when pica behavior is suspected of resulting in poor nutrition. Imaging studies may be warranted to determine the presence of ingested pica item(s). More extensive gastrointestinal work-ups may be necessary when further complications are suspected.

Behavioral Evaluation

A behavioral functional assessment is important in the treatment planning of pica, as it is important to distinguish what environmental factors may be maintaining or at least influencing the pica behavior. Functional assessments typically involve indirect methods such as starting with a focused interview of caretakers regarding situations where pica is observed and then not observed. The latter is just as important in treatment planning as determining when pica is most likely to occur. Functional analogue observations to specifically assess for pica would include safe replications of pica targets (“paint chips” made of cornstarch and water spread and dried on wax paper) along with the manipulation of common antecedent and consequence contingencies. Antecedents manipulated may be the presentation of a recent snack/meal or not, the presence of others (to determine whether there is a social component or not), the presence of toys or not (to determine whether pica is related to the impoverishment of environment), and the presence of appropriate food items (to determine whether pica is a substitution when food is not available). Consequence manipulation could include the attention of an adult’s attention for engaging in pica behavior, the access to a preferred item/activity contingent on pica, or the ability to escape a situation contingent on pica. Previous, albeit limited, work has suggested that pica may be reinforced by automatic reinforcement (Kern et al. 2006; Piazza et al. 2002). That is, the behavior of engaging in pica is reinforcing in and of itself or stated in less behavioral terms as sensory pleasing to the individual. While conducting such functional analyses whereby antecedent and consequence variables are experimentally manipulated is widely recommended prior to designing behavioral treatments, the use of functional analysis in the evaluation of pica has a limited research base to date (Kern et al. 2006; Mace and McKnight 1986; Piazza et al. 2002; Rapp et al. 2001). Nonetheless, a thorough behavioral assessment including functional analyses is accepted to be important in the development of empirically derived behavioral treatments that are least intrusive.

Additionally important for treatment planning is a preference assessment whereby reinforcers and punishers are empirically derived. Methods to determine possible reinforcers include indirect measures such as completion of a reinforcement inventory by a caregiver to direct measures (Hagopian et al. 2004). Direct measures have included observations of an individual approach to a stimulus when presented, duration of stimulus engagement, and the contingent presentation of stimuli to observe subsequent changes in rate of a chosen behavior (Fisher et al. 1994; Hagopian et al. 2004).

Treatment

The treatment of pica in ASD has a very limited empirical. As with other areas of the pica literature, there have been few, if any, large-scale treatment studies and the studies in the literature almost all combine individuals with ASD with those with ID and other developmental disabilities. Moreover, treatment studies have been nearly all either case reports or single subject studies with a small number of participants.

Pharmacological Treatment

Some very limited research has supported the use of medication, such as selective serotonin reuptake inhibitors (SSRIs) to treat pica (Stiegler 2005). Anecdotal report has suggested positive outcomes in children whose pica was treated with stimulant medications (Barrett 2008). At present, our knowledge base does not support the use of medication to target specifically pica.

Nutritional Treatments

Nutritional deficiencies have been linked to pica, especially iron and zinc. As discussed elsewhere in this chapter, there remains debate about whether nutritional deficiencies of these minerals may cause a person to engage in pica (eat iron- or zinc-containing substances), or whether that the ingestion of certain pica items results in subsequent mineral deficiencies. When iron and zinc are demonstrated to be deficit, supplementation is

warranted, and some have suggested pica behaviors may abate, but there is lack of empirical support for this.

Behavioral Treatment

Behavioral approaches have been the most common for individuals with pica and ASD and ID. The specific behavioral intervention should be based on the functional assessment with respect to environmental variables maintaining the pica. Such an assessment is described in a previous section on the evaluation of pica. Behavioral treatment procedures for pica may be categorized as preventive or antecedent strategies, reinforcement consequences, punishment consequences, and specific teaching procedures of a new skill. More likely than not, treatment will require a treatment package to include several behavioral procedures.

Preventive and antecedent strategies have been used to limit access to potential pica items from the environment. This may include increased straightforward approaches such as regularly vacuuming, storing trash cans away from the child, and timely waste disposal. Environmental enrichment as a preventive approach has also been used as well as teaching appropriate discrimination of what to place in the mouth (Johnson et al. 1994). Other prevent approaches have attempted to identify alternative, safe items which may be mouthed, chewed on in lieu of the pica item. Such an approach is appropriate when pica is suspected to be motivated by a need for sensory input, or in more behavioral terms, pica is automatically reinforced. Protective devices have also been used as a preventive approach. For example, arm splints and a facemask to prevent pica have been used. Such restrictive procedures should be used only in severe pica and as a temporary measure as a treatment program is being developed. Further, use of such procedures may be prohibited in some settings depending on local regulations.

In addition to prevention and antecedent strategies, reinforcement procedures have also been implemented to reduce pica behavior. These have included differential reinforcement procedures (differential reinforcement of other

behaviors, lower rates of pica behavior, or an alternative behavior). Noncontingent reinforcement has also been used. Reinforcement procedures presume reinforcers have been identified as part of the evaluation process which may compete from the reinforcing value of engaging in the pica behavior itself.

While a least restrictive approach should be considered, the seriousness of pica may justify consideration of punishment procedures to suppress the pica behavior. The treatment literature on the use of punishment includes a disproportionate number of individuals with severe and profound ID who had potentially life-threatening pica. Punishment procedures have included timeout, contingent presentation of aversive stimuli, overcorrection, positive practice, and visual screening, as well as contingent placement of protective equipment or other physical restraint (Bell and Stein 1992; McAdam et al. 2004). The consideration of the use of a punishment procedure should take into account the response of other approaches, the seriousness of the pica behaviors, and, again, local regulations regarding use of punishment procedures and consent requirements.

In addition to these behavioral procedures, teaching the individual to discriminate between edible and inedible items has been undertaken as a treatment approach to pica but in combination with a punisher (Bogart et al. 1995; Johnson et al. 1994). How the discrimination skill taught depends on the participant's level of development. The teaching of a replacement or alternative behavioral response behavior such as giving a pica to an adult and reinforcement for this has been described (Kern et al. 2006).

Pictorial Cues/Visual Supports (CR)

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

Pictorial cues or visual supports as used in language and cognitive therapy for individuals with autism are defined as any aid such as picture schedules, picture cards, symbols, communication boards, posters, models, visual scene displays, or videos that present information

visually. As suggested in the previous list, visual supports can be very low- or no-tech such as in picture communication boards or can be used in high-tech communication devices such as visual scene displays. Compensating for difficulties with attention, organization, sequencing, and processing of verbal information can be facilitated with visual supports. The most commonly used visual supports will be described here. They are visual schedules, communication boards, the picture exchange communication system, and visual scene displays. Communication boards are discussed as another entry in this encyclopedia and so will not be discussed in detail here. Suffice it to say that communication boards are used to augment the spoken communication of individuals with ASDs.

Visual schedules or schedule systems (Mesibov et al. 2002) or timetables (Bloomberg 1996) are designed to make an individual's agenda explicit. They have been used with children with autism spectrum disorders (ASDs) to provide them with a sense of security and consistency. Between-activity visual schedules are those which allow the user to see the activities that will be completed during any length of time such as a therapy session or an entire day. Within-activity visual schedules show the steps necessary to complete a task and are designed to help an individual become more independent.

The picture exchange communication system (PECS) was developed by Bondy and Frost to aid in the functional communication of nonverbal children with ASDs. There is a large literature on this communication system, and so a brief description of it will be provided here. PECS is a multiphase system that begins with requesting. The child is first taught to exchange a picture symbol for an object that is motivating and rewarding. This occurs through hand-over-hand assistance from another adult. The second phase of PECS training requires the child to be persistent in his/her requesting. The communication partner and the picture symbol are moved so the child must seek out the picture and seek out the communication partner to request a desired item. In the third phase of PECS, the child is taught to discriminate between picture

symbols. Phases four through six of PECS training involves helping the child combine symbols together to make sentences, respond to questions, and comment with the picture symbols. See Bondy and Frost (1994) for a more detailed description of PECS.

Visual scene displays are often whole pictures that represent an activity, place, or situation. They are useful for providing context for a communicative intention and aid in organization. For example, a scene of a park can be used for a child with autism. The picture can be either a real picture of the park the child frequents every afternoon, or a cartoon or line drawing of a generic park depending on the symbol transparency needs of the child. Given the picture, the child can request the swings, slide, or merry-go-round or the child can comment on the other children playing on the playground equipment. Drager et al. (2009) make the comment that visual scene displays are an interesting way to organize an augmentative and alternative communication system for individuals with ASDs because they allow for information to be presented as a whole and not in fragmented vocabulary items.

Historical Background

One of the earliest studies that involved the use of picture symbols with children with ASDs was conducted by Lancioni (1983). Two children were exposed to line drawings and were taught to interpret the line drawings and follow directions with them. Lancioni found that the children were successfully able to comprehend the symbols and accurately follow directions and that their ability to follow directions was generalized to other line drawings to which they had not previously been exposed. The use of picture symbols and visual supports for individuals with autism has grown to such an extent that at the time of this writing, when the words “picture symbol” and “autism” are fed into a search engine such as Google Scholar[®], nearly 4,500 results appear just since the year 2005.

Rationale or Underlying Theory

Hermelin and O’Conner (1970) were the first to state that some children with autism process visuospatial information better than auditory information. Additionally, it has been found that the memory of children with autism is superior for visual information compared to auditory information (Prior and Chen 1976). Finally, research on the attention of children with autism supports the notion that children with autism have difficulty selecting the most salient features of a stimulus (Frith and Baron-Cohen 1987). Overall, individuals with autism have been shown to have more difficulty with verbal information compared to visual information (Hodgdon 1995). Temple Grandin (1995) is an individual with autism. She states that she thinks in still pictures and in “videos” and that language-based information is difficult for her to process and retain. The use of other forms of augmentative communication for children with autism seems logical based on the strengths that children with autism possess. The use of sign language relieves the burden of having to process verbal information and builds on the strength of processing visuospatial information. The memory difficulties of children with autism can be alleviated by using picture communication symbols which do not require the child to rely on their own memories to create a message. If using picture symbols, children can attend to the symbols for as long as necessary to comprehend the information, alleviating the difficulties related to attention needed for verbal information transfer.

Although the use of picture symbols and visual supports are well supported by research, many laypersons fear that the use of these strategies will not allow oral speech to develop. The apprehension revolves around the idea that the individual with autism will use the visual supports as a crutch and will not need to use speech. In fact, the opposite has been shown to occur. Lloyd and Kangas (1994) and Ronski and Sevcik (1996) agree that visual supports serve to lower the linguistic and cognitive demands of speech production and reduce the stress associated with speech,

thereby facilitating speech development. Mirenda (2003) argues that the theory of automatic reinforcement is at play. When an individual with ASDs requests an item with a picture symbol, the communication partner verbally labels the item. The picture symbol and the verbal label occur so frequently together, and both are reinforced by the item; production of the verbal label and use of the symbol should increase.

Goals and Objectives

Like much of the field of AAC, the goal for the use of picture symbols and visual supports is functional communication. Because speech production may not be possible for all individuals with ASDs, delaying the introduction to other forms of communication can be damaging to the language, cognitive, and emotional development of these individuals and may hinder their social development as well.

Treatment Participants

Any individual who is unable to communicate to the level expected for their age is a candidate for augmentative and alternative communication of any form (Beukelman and Mirenda 2005). Therefore, because communication impairments are a hallmark of autism spectrum disorders (ASDs) (Mirenda 2009), many individuals with ASDs are candidates for a total communication approach.

Treatment Procedures

Some of the picture systems mentioned have very specific treatment procedures (see the PECS description). Others are more specific to AAC, and treatment procedures that are appropriate for the application of AAC are appropriate for the application of picture symbols and visual supports. Using the participation model (Beukelman and Mirenda 2005) as a guide, AAC interventions focus on allowing an individual with speech

impairment to participate in their environment to the same extent as that of their peers. Beukelman and Mirenda (2005) also provide strategies and recommendations for implementing AAC for both nonsymbolic and symbolic beginning communicators. Nonsymbolic beginning communicators are those who use nonsymbolic communication such as gestures, facial expression, cries, or grunts. Symbolic beginning communicators use some form of symbolic communication such as words (spoken or written) or symbols with low- or high-tech communication devices. The authors state “opportunity for communication is at least as important to the success of a communication intervention as the availability of an appropriate system” (p. 272). Additionally, the authors provide techniques related to shaping intentional communication, using scripted routines, providing natural consequences, and using structured instructional techniques such as the adapted strategic instruction model (A-SIM), structured practice, and conversational coaching.

Efficacy Information

A research synthesis was written by Wendt (2009) that discussed the application of picture symbols and visual supports for individuals with autism outside the domain of high-tech speech-generating devices. All of the studies included used a single-subject experimental design, and most of the studies focused on the ability of the individual with ASD to request objects or actions. A few studies focused on using visual supports to transition between activities, and one focused on recognition of orthographic symbols. The results of the review support the use of picture symbols for requesting. Children and adults were able to use picture symbols successfully to request a variety of objects and actions. Additionally, visual schedules were found to be helpful for individuals with ASDs in transitioning from one activity to another independently without the anxiety associated with inconsistent routines and without the need for constant prompting from another person.

Outcome Measurement

Because the goal of AAC use is functional communication, the outcome measurement should be the same. Functional communication will be defined differently based on the cognitive skills of the individual and the type of AAC system that is in place.

Qualifications of Treatment Providers

AAC (augmentative and alternative communication) interventions are most typically introduced by a speech-language pathologist. Unfortunately, many speech-language pathologists do not report having adequate training or education in the field of AAC (King 1998; Marvin et al. 2003; Simpson et al. 1999), and a survey of education programs for speech-language pathologists has uncovered a need for better education in this area (Ratcliff et al. 2008). Although this is the case, speech-language pathologists are the best equipped of all professionals who work with individuals with autism to provide intervention that includes AAC. A listing of speech-language pathologists who are certified by the American Speech-Language-Hearing Association can be found on their website. A few short questions posed to the speech-language pathologist can reveal whether they are comfortable with the area of AAC.

Picture Arrangement

Cate Kraper and Timothy Soto
Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Picture Arrangement is a subtest on both the Wechsler Intelligence Scale for Children-3rd edition (WISC-III; Wechsler 1991) and the Wechsler Adult Intelligence Scale-3rd edition (WAIS-III; Wechsler 1997). This subtest was dropped from the most recent versions of both the child and adult versions of the Wechsler tests (WISC-IV and WAIS-IV). In this subtest, individuals are presented with a series of cards in an incorrect order that must be placed in the correct order to tell a story that makes sense. The stories are similar to short comic strips, and placing them in order relies on the individual's ability to recognize the cause and effect relationship of events depicted in the cards. This task gives information about an individual's reasoning abilities, and performance is related to the ability to understand precursors and consequences of events. The pictures on the cards involve human characters and interactions, so to some degree the test draws on

the ability to understand antecedents and consequences of social interactions. Because of this, there has been a long-standing assumption that performance on Picture Arrangement is associated with social competence, especially given that performance on this subtest by individuals with autism is relatively weak compared to other subtests on the Wechsler tests (Lincoln et al. 1988). However, more recent evidence has suggested that performance does not in fact predict social understanding or competence (Campbell and McCord 1999; Lipsitz et al. 1993), and performance may instead be more related to general intelligence. Low scores may be related to difficulties with visual organization and visual acuity, or in anticipating events and their consequences; inattention to details and anxiety might also interfere with performance.

Picture Exchange Communication System

Eugenia Corbett¹ and Patricia Prelock²

¹Franklin County Home Health, St. Albans, VT, USA

²Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

The Picture Exchange Communication System (PECS) (<http://pecsusa.com/pecs.php>) is an aided picture-based augmentative intervention used to teach functional communication within a social context (Charlop-Christy et al. 2002; Frost and Bondy 2002). It requires an individual to spontaneously select a picture representing a desired item and exchanging that picture with a communication partner to retrieve the desired item. It is one of several interventions used to augment the communication of individuals with no or limited functional communication, particularly those with autism spectrum disorders (ASD).

Historical Background

Lori Frost and Andrew Bondy originally developed PECS at the Delaware Autism Institute for children with autism spectrum disorder (ASD) and other socio-communicative disorders who had limited or no functional communication. PECS was designed to address some of the problems associated with more traditional language training programs that require prerequisite skills such as motor and verbal imitation, visual attention, pointing, and initiation. It was also developed to circumvent the frequent difficulty children with ASD have with prompt dependency and obtaining a listener's attention (Bondy and Frost 1994, 1998; Frost and Bondy 1994). The first manual for implementing PECS was published in 1994. In 2002, Frost and Bondy updated the PECS by broadening their view on

the importance of establishing a foundation for communication training by systematically structuring the learning environment, redefining their intervention as the Pyramid Approach to Education (Bondy 2011), and emphasizing “functional activities and communication, powerful reinforcers and behavior intervention plans” (Frost and Bondy 2002, p. vii).

Rationale or Underlying Theory

PECS is designed to address the failure to initiate communication, a common deficit area for those with autism, which has implications for long-term outcomes related to the development of functional communication (National Research Council 2001). Further, as individuals with ASD often lack the motivation and the social skills (Ogletree et al. 2007) to communicate effectively in social contexts (e.g., failing to orient or attend to others, difficulty displaying affection and emotions in social contexts, and impairment in gesturing and pointing), a system that supports the development of social communication is critical. PECS offers a systematic approach to teach individuals to use functional communication skills to facilitate an exchange with a communicative partner. Bondy and Frost (1998) believe that an effective communication training system should use meaningful reinforcers through the application of request situations rather than labeling situations, emphasize spontaneous communication, avoid prompt dependency, and not require extensive training prior to the initiation of the system.

The underlying theoretical framework for PECS is grounded in the principles of behaviorism (Skinner 1953) and applied behavioral analysis (Baer et al. 1968), suggesting that the environment controls the learning of verbal and nonverbal communication skills and techniques such as modeling, prompting, and shaping can be used to facilitate that learning. PECS also capitalizes on the belief that many individuals with ASD are considered visual learners and a communication system that can effectively and efficiently incorporate visual and graphic symbols is likely to be more successful than those without a visual

emphasis (Mirenda 2001; National Research Council 2001). In addition, PECS uses a direct reinforcement system to motivate its communicators. That is, communicators with limited expressive language skills are taught to initiate nonverbal communicate to achieve their desired outcomes. PECS users learn that they can exchange a picture or icon for their actual desired item or activity. Thus, receiving what they requested rewards communicators.

Goals and Objectives

Bondy and Frost emphasize the importance of establishing educational objectives and activities that are functional and can be taught and utilized at school, home, and in the community. Intervention goals in the PEC system serve two broad communication functions, more directive communication attempts that serve as requests or commands and social communication attempts that include commenting, describing, and naming. Goals are established for each of the six phases of intervention with current levels of performance and the criteria for achieving each objective defined.

Treatment Participants

PECS has been utilized to support the communication of a variety of individuals. Originally, it was designed for young children with ASD (Bondy and Frost 2001; Ganz and Simpson 2004), but it has been successfully used with older children and adolescents who have limited expressive language or lack a functional communication system. Similarly, PECS has been applied to augment the communication of individuals with a range of language and developmental levels beyond ASD.

Although a formal assessment of who might be the most appropriate candidates for PECS is not available, the Pyramid Educational Consultants pose several questions for consideration when identifying possible candidates. These include whether or not a person has a functional

communication system, the extent to which their communication attempts are understood, how effective their communication system is at addressing their wants and needs, and whether their current system facilitates spontaneous communication and the ability to respond to a variety of questions.

Treatment Procedures

PECS has some advantages over other communication interventions in that communicators are not required to exhibit prerequisite skills such as attention and eye contact nor are they required to demonstrate comprehension of the pictures or icons used prior to initiating the intervention. PECS focuses on developing a number of key receptive and expressive language skills (Frost and Bondy 2002). Receptively, PECS targets the ability to respond to directions, follow visual cues, and follow a direction to wait. Expressively, PECS emphasizes requesting help, a break, or desired item or activities and rejecting or affirming offers of items or activities. Instructors determine which skills the communicator needs and then plan to address these within the six phases of PECS.

Prior to implementation of the six intervention phases, a reinforcer assessment is completed with the individual for whom the intervention is being used to determine what items are highly preferred, preferred, and nonpreferred. Individualized reinforcers as well as the corresponding pictures and/or icons that match the communicators' desired items are determined by the communicators' interests, needs, and wants. Input is gathered from parents or caregivers and probing the individual's preferences from 5 to 8 selected items (Frost and Bondy 1994).

Following the reinforcer assessment, *Phase I: Teaching the physically Assisted Exchange* is initiated. This phase requires two trainers: one person who serves as the communication partner and receives the picture and one who provides, at least initially, hand-over-hand assistance. The goal of Phase I is to have the communicator spontaneously pick up a picture of a highly preferred

item, reach toward the trainer, and release the picture into the trainer's open hand (Frost and Bondy 1994).

In *Phase II: Expanding Spontaneity*, the distance between the communicator and the communication board and the communicator and the trainer is increased. Spontaneity is expanded to increase communicative persistence so that the individual goes to his/her communication board, removes a picture, finds the trainer, and releases the picture into the trainer's hand (Bondy and Frost 1998; Frost and Bondy 1994).

Phase III: Simultaneous Discrimination of Pictures teaches the communicator to discriminate between pictures. The communicator requests a desired item by going to his/her communication board, selects the picture representing the desired item from an array, moves to the communication partner, and releases the picture into the partner's hand (Frost and Bondy 1994).

Phase IV: Building Sentence Structure teaches the communicator to request using the carrier phrase, "I want." The individual selects a desired picture and places it on a sentence strip next to a picture depicting "I want ____" to complete the phrase. The individual then gives the entire sentence strip to the communication partner.

In *Phase V: Responding to "What do you want?"* the communicator is taught to respond to this question using delayed prompting. Throughout the communicator's daily activities, he/she is expected to spontaneously request desired items and answer the "What do you want?" question.

The final phase, *Phase VI: Commenting in Response to Questions*, requires the communicator to respond to different questions (e.g., "What do see?" "What do you have?") using carrier phrases (e.g., "I see ____." "I have ____.") to teach communicative functions like labeling or naming. The communicator is taught to respond to the communication partner's questions related to a particular referent such as pulling a car out of a bag and asking, "What do you see?" with the expectation that the communicator will select the correct picture for the item and create a sentence strip that says "I see car."

Beyond Phase VI, communicators are taught a variety of language concepts (e.g., location, verb

concepts, attributes) using the basic PECS principles. A variety of teaching procedures that fall under the umbrella of applied behavior analysis are used to facilitate the success of the communicator during the training phases. These include the use of backward chaining, incidental training, shaping, discrete trials, delayed prompting, and discrimination training (Bondy and Frost 1994).

Efficacy Information

Over the last 20 years, several studies have investigated the effectiveness of PECS as a communication intervention for children with ASD. PECS has been investigated in small groups and single subject designs including both efficacy (those occurring in controlled settings like research labs and clinics) and effectiveness (those occurring in natural settings like home and school) studies (Prelock et al. 2011). Research has focused primarily on children with ASD 18 months to 12 years of age with limited investigation of older children, adolescents, and adults. Some comparisons of PECS to other interventions (Beck et al. 2008; Tincani 2004; Yoder and Stone 2006) exist, although this is an area of research requiring further examination to determine what outcomes might best be facilitated by PECS versus other interventions.

A number of functional communication outcomes have been reported following PECS training ranging from speech facilitation (Bondy and Frost 1994, 1998; Ganz et al. 2008) and increased initiations (Carr and Felce 2007a, b; Howlin et al. 2007) to gains in joint attention, eye contact, and toy play with a reduction of problem behaviors (Charlop-Christy et al. 2002; Yoder and Lieberman 2010). In addition, results have revealed increases in vocabulary (Anderson et al. 2007; Jurgens et al. 2009; Magiati and Howlin 2003; Yoder and Stone 2006) and utterance length (Charlop-Christy et al. 2002; Ganz and Simpson 2004; Jurgens et al. 2009). Maintenance of speech gains and generalized use of trained and untrained functions across settings have also been documented (Charlop-Christy et al. 2002; Kravitz et al. 2002; Schwartz et al. 1998; Yokoyama et al.

2006). Significant increases in spontaneous communication using pictures, speech, or both were found in a randomized control trial with 84 school children, 4–10 years of age following the use of PECs (Gordon et al. 2011).

Ostry et al. (2008) suggested that PECS should be part of a multimodal communication system to facilitate joint attention and question asking, and Tien (2008) reviewed 13 studies with results suggesting PECS effectively improves functional communication in children with ASD. A meta-analysis of PECS research completed between 1994 and 2009 found it to be a promising intervention for facilitating communication in children 1–11 years of age, although speech gains were less consistent (Flippin et al. 2010). Ganz et al. (2012) also completed a meta-analysis with similar findings that PECS was most successful in supporting functional communication outcomes and particularly for preschool children with ASD.

PECS appears to be an appropriate strategy for supporting young children at the early stages of communication (Prelock et al. 2011). More research, however, is needed to identify the profiles of those children most likely to benefit from PECS versus other intervention methods.

Outcome Measurement

No specific tools are used to measure treatment outcomes, although consistent with the principles of applied behavior analysis, PECS incorporates a data-based system to measure progress across all phases of the program. An 80 % or higher correct response rate for a minimum of 3 days is required for a communicator to move across each phase of PECS (Frost and Bondy 1994).

Practitioners and researchers have been interested in the development of spoken language following the implementation of PECS. Frost and Bondy (1994) reported that children learning PECS began speaking. Ganz and Simpson (2004) confirmed that spoken language sometimes follows training in PECS. Interest also exists in the impact of PECS on reducing behavior problems and aberrant responses (Charlop-Christy et al. 2002; Ogletree et al. 2007).

Qualifications of Treatment Providers

Speech-language pathologists, teachers, families, and others can use PECS in a variety of settings as it does not require complex or expensive technology or equipment, materials are readily available, training is accessible, and the intervention is manualized.

Pyramid Educational Consultants offer PECS training globally. Providers seeking implementation certification status (<http://www.pecsusa.com/certification.php>) must provide proof of attendance at a basic PECS workshop and must demonstrate competency in implementing the six phases of PECS, error correction procedures, implementation during functional activities, writing PECS lessons and summaries, and data collection. Those receiving a *PECS Implementer Certificate* can renew their certificate every 3 years. Pyramid Educational Consultants have explicit rules and guidelines for those who complete each level of PECS training. They also provide training for supervisors. This is an advanced training for individuals who are skilled in applying the Pyramid Approach to PECS implementation in the worksite and with those who have completed the basic PECS training.

Synonyms

1-[1-[4,4-bis(p-fluorophenyl)butyl]-4-piperidyl]-2-benzimidazolinone; Orap

Definition

Pimozide is an antipsychotic in the diphenylbutylpiperidine class with the chemical formula $C_{28}H_{29}F_2N_3O$. This drug was initially FDA-approved in 1984 for the treatment of severe tics associated with Tourette syndrome. It is used outside of the United States for schizophrenia and has also been found to be effective in the treatment of monosymptomatic hypochondriacal psychosis, body dysmorphic disorder, metastatic melanoma, trichotillomania, and trigeminal and postherpetic neuralgia. Adverse effects include extrapyramidal reactions, akathisia, dystonia, tardive dyskinesia, neuroleptic malignant syndrome, menstrual irregularities, and galactorrhea. The drug has also been reported to have adverse cardiac effects. Unexpected deaths have been reported in patients using high doses of this drug.

Pincer Grasp

Tina R. Goldsmith
Center for Development and Disability,
University of New Mexico, Albuquerque, NM,
USA

Definition

When a child employs a pincer grasp, the tips of the thumb and index finger are used in opposition to pick up and manipulate small objects. The ability to perform this task is a milestone of fine motor development that typically emerges before a child's first birthday. Prior to the emergence of this skill, infants grasp objects in more rudimentary ways. Ordinarily, by 6–7 months, objects are raked into the palm with the fingers. By 8–9 months, the thumb and radial fingers are used to grasp and pick up small objects. Then, by 10–12 months, the fine pincer grasp appears. It can be tested by allowing a child to pick up a small object (e.g., a piece of breakfast cereal) from a flat surface. Once this skill is added to a child's fine motor repertoire, their ability to explore their world through object manipulation is greatly increased.

Definition

Pivotal response training[®] (PRT[®]) is an individualized, comprehensive treatment model that uses the child's motivation to present learning opportunities within their natural environment. It was developed by Lynn and Robert Koegel and initially called the natural language paradigm (Koegel et al. 1987). Grounded in applied behavior analysis and developmental approaches, PRT[®] targets pivotal areas such as motivation, responsivity to multiple cues, self-management, and self-initiations. Focusing on these pivotal areas results in collateral gains in untargeted areas and generalized sustained improvement in language, behavior, and social outcomes. Its comprehensive approach encourages consistent and coordinated programming across the child's contexts, with particular focus on parent education. Parents play an integral role in the habilitation process and receive training in PRT[®] using a collaborative, ecocultural approach. Through this partnership-based model, parents identify clinically meaningful goals and intervention strategies that can be easily incorporated into their already existing daily routines. The aim of PRT[®] is to improve the quality of life for children with autism spectrum disorders by creating opportunities to lead meaningful lives in fully inclusive settings.

Reproductive Sciences, Yale University School of
Medicine, New Haven, CT, USA

Definition

If we could noninvasively analyze the detailed neuroanatomy of all newborns at a cellular, synapse by synapse level, we might be able to identify those children who will go on to have an autistic spectrum disorder (ASD). As that is unlikely to be possible anytime soon, doctors seek surrogates that can make the same diagnoses. Luckily, the placenta, an organ that is often routinely discarded at birth, may be able to identify those babies who will exhibit overt signs of autism months or years later.

The human placenta is not only an integral part of the fetus during all of pregnancy, but it also shares in the vast majority of cases the exact genetic makeup of the fetus. As such, it offers the potential to reveal abnormal morphologic patterns that may be at the basis of ASD and other genetic and developmental abnormalities.

Historical Background

Formation of the Placenta

Humans start off as a symmetrical ball of cells. Even as our first few dozen cells begin to separate into an inner cell mass (which will become the embryo, fetus, and eventually baby) and the trophoblasts (which will become the placenta), genes are regulating the creation of the developmental axes that will form the basis of the entire organism (Kliman 1999). Defects in the genes that regulate these processes lead to a wide range of embryonic, fetal, and neonatal defects from minor cosmetic

abnormalities to disasters that terminate pregnancy within a few days to weeks after fertilization.

By 21 days after fertilization, the trophoblasts have begun to sort themselves into what will become the treelike structures that make up the placenta: the chorionic trees, branches, and villi (Fig. 1). The terminal villi (from the Latin for shaggy hair) are fingerlike structures that are covered with a double cell layer. This trophoblast bilayer is made up of an inner cytotrophoblast layer made of single nucleated cells and an outer syncytiotrophoblast layer made of giant multinucleated sheets (Fig. 2). Starting with purified cytotrophoblasts, we demonstrated using in vitro time lapse cinematography that cytotrophoblasts fuse to form syncytiotrophoblast (Kliman et al. 1986) (Fig. 3), an observation that has been confirmed in situ (Huppertz et al. 2001). The critical

conclusion from these studies is that only the cytotrophoblasts proliferate, making the growth of the syncytiotrophoblast layer completely dependent on the absorption of fusing cytotrophoblasts (Fig. 4).

Current Knowledge

Trophoblast Inclusions

The relative rates of cytotrophoblast proliferation and incorporation into the outer syncytiotrophoblast layer appear to determine the morphology of the fingerlike chorionic villi (Huppertz et al. 2001; Kliman and Segel 2003; Rejniak et al. 2004). In the normal placenta, new villus branches are formed by outward bending bulges of the trophoblast bilayer (Fig. 5). However, when these critical processes go awry, the

Placenta, Fig. 1 *Diagram of the human placenta.* The placenta, which is part of the fetus, attaches to the maternal decidua via the anchoring villi. The maternal blood is injected into the intervillous space where it circulates around the chorionic villi and then returns to the maternal circulation via the endometrial veins. The fetus pumps its blood into the placenta via the umbilical arteries, which

branch in the chorionic plate and eventually dive down to form the villus trees. The fetal circulation terminates in the fingerlike chorionic villi, which are covered by a layer of trophoblast cells (see Fig. 2). (From Moore KL, *The Developing Human*, 4th edition, WB Saunders, 1988, used with permission)

bilayer can inappropriately bulge inward into the villi, creating invaginations (Fig. 6) and trophoblast inclusions (Fig. 7) that can be readily detected upon histological examination of sectioned placental tissue.

The basis of trophoblast invaginations and inclusions, therefore, appears to be an imbalance between the rate of cytotrophoblast proliferation

Placenta, Fig. 2 Diagrammatic cross section of first-trimester chorionic villus. The villus core of villi contains fetal capillaries embedded in a loose matrix which contains fibroblasts and macrophages (also called Hofbauer cells). In the first trimester, a villus cross section reveals two distinct trophoblast layers, the outer syncytiotrophoblast layer which is in direct contact with maternal blood and the inner cytotrophoblast layer, the stem cell of the placenta and the source of new trophoblasts. (Modified from Moore KL, The Developing Human, 4th edition, WB Saunders, 1988, used with permission)

and fusion (Rejniak et al. 2004). This could be the result of either an increased rate of proliferation – due to either endogenous genetic factors within these cells or exogenous factors such as increased exposure to paracrine or endocrine growth factors – or the result of a decreased rate of fusion – due to decreased production of the factors that facilitate cell fusion. Endogenous cell proliferation rates may be affected by genes that regulate the mitotic cycle, such as the cyclins (Gillett and Barnes 1998). Equally potent are hormones that regulate cellular proliferation, such as growth hormone and insulin. Abnormalities of cytotrophoblast fusion have been shown in the placentas of Down syndrome (trisomy 21) children, showing a direct relationship between this particular genetic disorder and placental morphogenesis (Malassine et al. 2010).

Understanding how trophoblast invaginations and inclusions are formed helps to identify them in placental tissues and leads to criteria for diagnosing these dysmorphic features. In almost all cases of invagination, there is an increased number of cytotrophoblasts at the point of infolding compared to the density of cytotrophoblasts away from the invagination (Fig. 8). Likewise, careful examination of a trophoblast inclusion reveals a central region of syncytiotrophoblasts, surrounded by cytotrophoblasts (Fig. 8). Like an epidermal inclusion cyst, which continues to get larger and larger over time, the cytotrophoblasts continue to proliferate and fuse with the adjacent

Placenta, Fig. 3 *In vitro* conversion of cytotrophoblasts into syncytiotrophoblasts. Individual cytotrophoblasts (left) migrate like amoeba, eventually making contact with each other. Once in contact, the cytotrophoblasts form aggregates (middle), and in time, the cells fuse to form syncytiotrophoblasts. Eventually, all the cytotrophoblasts have merged and fused to make a large

syncytiotrophoblast (right). (From Kliman HJ, Nestler JE, Sermasi E, Sanger JM, and Strauss JF III. (1986) Purification, characterization and *in vitro* differentiation of cytotrophoblasts from human term placentae. *Endocrinology* 118: 1567–1582, used with permission. Copyright 1986, The Endocrine Society)

Placenta, Fig. 4 Cytotrophoblast proliferation and fusion. Cytotrophoblasts (blue) either proliferate to increase the number of trophoblastic stem cells (blue arrows) or occasionally fuse upward (gold arrows) into the multinucleated syncytiotrophoblast layer (red). The balance of these two processes – proliferation and fusion – determines the overall morphology of the placenta's chorionic villi (see also Fig. 5)

Placenta, Fig. 5 Proliferation fusion model. A model illustrating the different ratios of proliferation (P) and fusion (F). Cytotrophoblasts (pink circles) proliferate and intermittently fuse into the upper syncytiotrophoblast layer (blue bars). Stability (relative flatness) of the bilayer is maintained at, or near, an ideal ratio: $P = 2F$. Normal outward budding (evagination) is observed from the ratio: $P < 2F$, while an abnormal trophoblast inclusion (invagination) results from the ratio: $P > 2F$. (Kliman HJ, Segel L. (2003) The placenta may predict the baby. *J Ther Biol*, 225: 143–145, used with permission)

syncytiotrophoblasts, which in some cases leads to very large trophoblast inclusions (see Fig. 7d). Adherence to the criteria of identifying increased numbers of cytotrophoblasts along the invagination and around the syncytiotrophoblast core of an inclusion helps to distinguish trophoblast invaginations and inclusions from tangential sections of curved chorionic villus surfaces.

Although trophoblast inclusions were first described as a marker of triploid gestations (a complete extra one set of chromosomes) (Szulman et al. 1981), it is now appreciated that the presence of trophoblast inclusions in placentas is associated with a long list of genetically abnormal gestations, including tetraploidy (a complete extra two sets of chromosomes), trisomies (an extra individual chromosome, such as trisomy

21 or Down syndrome, trisomy 18, and trisomy 13), Turner's syndrome (female with one X chromosome missing), and even genetic diseases without obvious chromosome abnormalities (Honore et al. 1976; Novak et al. 1988; Silvestre et al. 1996; Szulman 1984; van Lijnschoten et al. 1993). Thus, many different genetic defects manifest themselves in the placenta as trophoblast inclusions. Since cytotrophoblast proliferation and absorption is no doubt regulated by many genes, it appears that abnormalities in any part of these multigene processes may result in these villus dysmorphic features.

Frequency of Trophoblast Inclusions

Fewer than 3% of placentas from uncomplicated, normal gestations manifest trophoblast inclusions. But 70% of placentas of fetuses with known chromosomal abnormalities exhibit inclusions (Kliman et al. 2003). Since the presence of a normal karyotype does not exclude the possibility of a genetic defect (e.g., cystic fibrosis, Tay-Sachs, sickle cell disease), it should not be surprising that trophoblast inclusions are also seen in cases with a normal karyotype. The most common example of the later situation is a spontaneous pregnancy loss where the karyotype is normal, but clearly, there is something abnormal about the gestation. The genetic basis of such losses is reinforced by the finding of both a high recurrence risk for these families and the fact that the losses almost always occur at the same gestational age for each particular family, suggesting a specific programming error.

The more severe the genetic abnormality, or the earlier the pregnancy loss, the more inclusions are found (Fig. 9). This is consistent with studies that have concluded that over 90% of first-trimester losses are secondary to genetic causes (Zhang et al. 2009). As pregnancies progress from the first to the third trimester, the likelihood of a genetic basis for a pregnancy loss decreases but does not go to zero even at term. Not surprisingly, the number of trophoblast inclusions seen in cases that reach term are fewer than those that terminate early in pregnancy. This is most likely related to the severity of the genetic abnormality, with the most severe terminating before 13 weeks of gestation.

Placenta, Fig. 6 *Trophoblast invaginations.* (a, b) Trophoblast invaginations forming cleft-like structures. Note the many cytotrophoblasts lining the invaginations (arrowheads) and the fewer cytotrophoblasts underlying the normal bilayers (*). (c) Invagination ending in an area of increased syncytiotrophoblasts (arrow). Even though

the bilayer is invaginated, syncytiotrophoblasts still form. (d) Bulb-like prominence of syncytiotrophoblasts at base of an invagination (arrow). (Kliman HJ, Segel L. (2003) The placenta may predict the baby. *J Ther Biol*, 225: 143–145, used with permission)

Placenta, Fig. 7 *Trophoblast inclusions.* (a) Trophoblast inclusion within the villous core. (b) Trophoblast inclusion with a prominent syncytiotrophoblast layer and a lone cytotrophoblast

(arrowhead). Fetal vessels (V). (c) Chorionic villous with four prominent trophoblast inclusions (arrows). (d) Trophoblast inclusion with very expanded syncytiotrophoblast component (arrow). (Kliman HJ, Segel L. (2003) The placenta may predict the baby. *J Ther Biol*, 225: 143–145, used with permission)

Placenta, Fig. 8 *Formation of trophoblast invaginations and inclusions.* (a) Histologic section of a placental villus which exhibits both a trophoblast invagination (I) and inclusion (TI). Note the increased numbers of cytotrophoblasts (arrow heads) beneath the syncytiotrophoblast layer in the region of the invagination and their paucity away from the invagination (*). When an invagination is sectioned perpendicular to its long axis (S-S), it appears as an inclusion (TI), with dark syncytiotrophoblast nuclei in its center surrounded by

cytotrophoblasts (arrow heads). IVS Intervillous space. (b) Diagram of a villus cross section showing the outer syncytiotrophoblast layer (blue) and inner cytotrophoblast layer (pink cells) with a trophoblast invagination (I) and inclusion (TI) illustrating the relevant morphology and disposition of cytotrophoblasts in the region of the invagination. (From Anderson GM, Jacobs-Stannard A, Chawarska K, Volkmar FR, Kliman HJ. (2007) Placental Trophoblast Inclusions in Autism Spectrum Disorder, *Biological Psychiatry*, 61:487–491, used with permission)

The only documented nongenetic cause for trophoblast inclusions appears to be gestational diabetes. In such cases, it is believed that increased glucose and insulin levels lead to increased cytotrophoblast proliferation, which as described above, would lead to invagination of the trophoblast bilayer. This is consistent with the observation that cultured cytotrophoblasts grow better in high glucose media compared to normal media (Kliman et al. 1986). It is also of interest that diabetics have a much higher fetal anomaly rate (Correa et al. 2008), suggesting that the high glucose insulin environment leads not only to abnormalities in the placenta but also in the fetus. This has been confirmed in rat gestations where it has been shown that high glucose levels alone can lead to both deformed fetuses and pregnancy terminations (Reece et al. 1994).

Trophoblast Inclusions and Autism

It was in the context of trophoblast inclusions as a general marker of genetic and developmental abnormalities that the association of trophoblast inclusions and autism was first suggested. The linkage was first observed anecdotally in two cases of Asperger's syndrome, which was then followed by a retrospective study. Trophoblast inclusions were found in significantly more

cases of ASD than would be predicted from the normal population (Anderson et al. 2007).

This result fits into the consensus view that ASD is largely genetically based. It also suggests that this seemingly polygenetic, heterogeneous condition may ultimately be caused by subtle abnormalities in common morphogenetic processes, such as bilayer folding.

A Problem of Folding

There are only a few developmental processes in the embryology tool box. These include cell proliferation, cell death, cell migration, cell hypertrophy, differentiation, fusion, and cellular dissociation. With these tools, all the various organs and body parts are made. One of the common problems in development is how to increase surface area. There are two basic solutions to this problem: increased branching or increased folding. In both cases, these are most often achieved by differential growth of layers of cells, which due to increased tension being built up in one layer or another, results in bending. This is exactly how the placenta forms new buds and villi to make the villus tree. It is also how the heart forms, the bronchi branch in the lung, the kidney tubules form, the gut surface area increases, and most dramatically how the brain, especially the human brain, fits into the skull.

Placenta, Fig. 9 *Trophoblast inclusions as a function of genetic abnormality severity.* Normal placentas rarely exhibit trophoblast inclusions. As the degree of genetic abnormality increases, the more trophoblast inclusions can be identified per unit area of placenta examined. The earlier the pregnancy loss, the more frequent the inclusions. Many pregnancy losses reveal normal karyotypes; however, a significant number of trophoblast inclusions can be seen in many of these cases. The trisomies (e.g., trisomy 21, 13, 18) may or may not lead to an early pregnancy loss, depending on which chromosome is affected. In very abnormal gestations, such as triploidy and tetraploidy, as many as 50 or more inclusions per slide can be seen. ASD, a subtle condition that does not lead to pregnancy loss, usually exhibits only 1–3 trophoblast inclusions per placenta slide examined

Since the upper limit of human skull diameter is directly related to the size of the female pelvis, increases in brain surface area could only be achieved by folding. And the human brain is one of the most folded brains in the animal kingdom (Hilgetag and Barbas 2006). Behind this folded structure are the cellular processes that lead to differential growth in the many neural layers that make up the brain. Could the developmental abnormalities that lead to abnormal folding and trophoblast inclusions in the placenta also be at work in the brains of ASD children?

Researchers have demonstrated significantly abnormal brain folding in children on the autism spectrum using surface mapping and magnetic resonance imaging (MRI) (Awate et al. 2008; Kates et al. 2009; Nordahl et al. 2007). These abnormalities may in part explain the observation of increased head size in ASD children (Awate et al. 2008; McCaffery and Deutsch 2005). Basically, with less folding, the brain tissue has no

other option but to expand the skull to make up for the less compact nature of the neural tissue. Translating this gross macroscopic observation to cellular processes and ultimately to abnormal behaviors is much harder. However, neuropathologists have described abnormalities in ASD children at the tissue level of the brain that may be associated with these macroscopic changes (Bauman and Kemper 2003, 2005; Kemper and Bauman 1998; Whitney et al. 2009).

Future Directions

If one of the basic pathologies in ASD is related to problems in tissue folding, then we should see evidence for this in any tissue where folding is a critical part of the anatomy or function of that tissue. Some organs may be impervious to low frequencies of misfolding, such as the liver, which does not have a critical requirement for multilayer cellular organization. Other organs, such as the gut, may not function as well if its folded structure is disrupted. If commonalities can be ascertained in cases of ASD, then candidate genes could be sought that control and regulate these processes. Further, in the future, one might anticipate that genetic or medical interventions might be forthcoming that can ameliorate the abnormalities that may exist in ASD children. In the meantime, knowing that trophoblast inclusions are related to ASD could lead to early identification and intervention before overt symptoms arise.

Definition

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by social and communication deficits and repetitive behaviors (Lyall et al. 2017). There are currently no biomarkers for ASD and diagnosis is based mainly on children's altered behaviors, which is not evident until 2–4 years. Yet, early detection and intervention is important for successful ASD management. Therefore, there has been a heightened interest to identify reliable markers that can facilitate early risk assessment and be a potential target for therapeutic interventions (Ashwood et al. 2006).

The precise mechanism underlying ASD's pathophysiology is still elusive; however, emerging evidence suggests that both metabolic (Li et al. 2016; Panjwani et al. 2019) and immune system (Brucato et al. 2017; Raghavan et al. 2019b) may be implicated. The interface between immune and nervous system is complex, and extensive communication between these systems occur during health and disease states (Ashwood et al. 2006). The immune system, once thought to

be only responsible for defending against invading pathogens, has now shown to play an important role in neurodevelopment and regulation of neural plasticity (Heuer et al. 2019). Several studies have suggested immune abnormalities in those with ASD (Ashwood et al. 2011; Ghaffari et al. 2016; Molloy et al. 2006; Raghavan et al. 2018). This is also supported by postmortem studies that have reported an increase in pro-inflammatory cytokines in the brain of subjects with ASD (Vargas et al. 2005).

Adipose tissue, beyond its energy storing capabilities, functions as a highly active endocrine organ that orchestrates inflammatory response through the production of adipocytokines (Hansen-Pupp et al. 2015; Mazaki-Tovi et al. 2009a; Villarreal-Molina and Antuna-Puente 2012). Adipose tissue releases a variety of inflammatory factors including leptin, adiponectin, and resistin that control various physiological systems (Ghaffari et al. 2016). Adiponectin is the most abundantly produced cytokine by adipose tissue, which exerts anti-inflammatory action on a number of cell types (Mazaki-Tovi et al. 2009b; Ouchi and Walsh 2007). It is downregulated in response to pro-inflammatory cytokines and oxidative stress (Michalska-Jakubus et al. 2019). Adiponectin has neuroprotective functions, with evidence suggesting altered adiponectin levels in neurologic disorders with an underlying etiology involving metabolic and inflammatory pathways (Ghaffari et al. 2016; Molloy et al. 2006). Adiponectin receptors are highly expressed in different brain regions, and its presence in the central nervous system has been attributed to neuroprotective and antidepressant properties (Bloemer et al. 2018).

Emerging research has assessed whether adiponectin levels are altered in individuals with ASD. A cross-sectional study conducted in Japanese boys reported that adiponectin levels are reduced in subjects with ASD than age-matched neurotypical controls (Fujita-Shimizu et al. 2010). The authors also reported a negative correlation between adiponectin levels and an abnormality in social interactions but not with restricted or repetitive behaviors (Fujita-Shimizu et al. 2010). Another cross-sectional study conducted in a

tertiary health facility reported no difference in adiponectin levels between ASD subjects and controls, who were matched for age, sex, and maternal age; however, they showed a negative correlation between adiponectin levels and Social Responsiveness Scale, a measure of social impairment in a social setting (Rodrigues et al. 2014). A longitudinal study conducted in pubertal children showed that adiponectin levels did not significantly differ between age- and sex-matched neurotypical and ASD children at baseline and 1 year after (Blardi et al. 2009). All these studies assessed adiponectin in children diagnosed with ASD and it was unclear if alteration in adiponectin levels preceded ASD diagnosis. A prospective birth cohort study published recently answered this question; this US-based study showed that both cord and early childhood adiponectin levels prior to ASD diagnosis were inversely associated with ASD risk (Raghavan et al. 2019a). Specifically, the association between cord adiponectin levels and ASD was robust suggesting that alteration in adiponectin levels may have its origins in fetal life.

In summary, the available literature suggests that adiponectin levels may be altered in subjects with ASD; however, the current literature is limited by small sample sizes, cross-sectional study design, heterogeneity in age of adiponectin measurement, and lack of adjustment of key confounders – all of which reduce the confidence in the strength of association. Adiponectin as an ASD biomarker is not yet ready for prime time, and more prospective birth cohort studies are warranted to understand the role of adiponectin as well as other adipocytokines such as leptin (Raghavan et al. 2018), in the development of ASD and underlying mechanisms.

Structure

Autism spectrum disorders are characterized by profound impairments in language acquisition and social interaction that are often comorbid with repetitive behaviors and sensory and motor abnormalities. Communicative and social skills emerge in early childhood and grow exponentially in complexity. The establishment of appropriate neural circuitry in the cerebral cortex subserving language acquisition, social interaction, and indeed, all aspects of cortical function, including vision and motor control, relies on the proper execution of genetic programs that regulate neural proliferation, migration, differentiation, axon guidance, and recognition of synaptic targets. A characteristic conserved between these disparate systems is that this circuitry is ineffective at birth. Sensory experience within specified sensitive or so-called “critical” periods during development sculpts the fine structure and function of cortical circuitry. However, the timing and influence of these critical periods varies dramatically among the functional domains of the cerebral cortex. This entry examines recent advances in our understanding of how autism-candidate genes regulate neural growth, synaptic plasticity, and the closure of critical periods.

Anatomical Plasticity of Neural Structure

The establishment of precise neural circuitry in the cortex hinges on five major events. First, neurons must be born in correct numbers. Second, these neurons must migrate to appropriate locations to establish the basic lamination of the cortex. Third, these neurons must grow specialized processes – dendrites that integrate information coming into the neuron and axons that provide the information output to other neurons in the cortical network. Fourth, axons must identify appropriate target dendrites and establish synapses. Fifth, these newly formed synapses are stabilized or eliminated by neural activity largely driven by sensory experience. In the cortex this last step of experience-dependent changes in the number and strength of synapses peaks during critical periods. In this entry, we examine recent

work on synaptic and circuit plasticity in mice with genetic mutations in genes associated with autism.

Function

Critical Periods of Experience-Dependent Plasticity in the Developing Human Brain

Critical periods are present in all areas of cortex examined from the evolutionarily earliest primary sensory cortices to the phylogenetically more recent frontal cortices. Perhaps the most well known examples are critical periods in sight and language. Poor vision during childhood results in a permanent reduction in high acuity vision – a condition known as amblyopia. In children born with congenital cataracts, for example, restoration of optical clarity through the lens will restore sight if the surgery is completed before about age 5. The older the age at treatment the worse the final outcome (Holmes et al. 2011). If corrective surgery is delayed past puberty the patient will remain effectively blind to that eye, despite the restoration of normal optical clarity through the eye and otherwise normal signal transduction in the retina. This permanent loss of sight results from the development and ultimate crystallization of cortical circuitry exposed to poor vision. Vision, therefore, profoundly shapes cortical circuitry, effectively establishing our sense of sight by its actions on cortical connectivity, but only during a limited period of adolescence. Cataracts that form in adults do not induce permanent deficits in sight once removed. Similarly, language acquisition is entirely dependent on exposure to language and its actions on cortical wiring. Socially isolated children fail to acquire normal language if initial exposure occurs past puberty (Fromkin et al. 1974). A second language learned after puberty is heavily accented with improper intonation, whereas fluency of speech and comprehension are readily attained if the second language is learned before 7 years of age (Johnson and Newport 1991). The critical period for learning social interactions, which is heavily dependent on frontal cortical circuitry, is not well defined, but in humans it can be argued that it extends throughout life.

Typical Development of Human Frontal and Temporal Cortex

The closure of cortical critical periods is tied to cessation of neural growth, the strengthening of cortical inhibition (Hensch 2005), and the establishment of axonal myelination (McGee et al. 2005). In frontal cortex, the region most severely affected in autism and the region of the brain that regulates executive function, neurons are remarkably immature at birth. Dendrites of frontal cortical pyramidal neurons are very rudimentary, extending to perhaps 3% of their ultimate adult size (Huttenlocher 1990). Dendritic growth proceeds slowly, reaching 35% of adult size by 6 months of age, 50% of final size by 2 years of age, and are adult-like by 7–10 years of age (Huttenlocher 1990). The slow, progressive growth of dendrites and concomitant increase in neuropil are reflected in functional brain imaging studies demonstrating a progressive thickening of frontal gray matter that peaks at about age 12 (Giedd et al. 1999). Notably, the language areas of frontal and temporal cortex, another region that is thought to malfunction in autistic patients, continue to thicken well past puberty (Sowell et al. 2004). The prolonged development of these cortical areas may reflect their phylogenetically recent emergence in the forebrain (Hill and Walsh 2005). Relative to phylogenetically older sensory cortices, frontal cortex has experienced a tremendous expansion from basal shrew-like mammals through primates and ultimately humans. Paralleling this expansion is the emergence of complex social structure and language – both of which require decades of learning to master.

The establishment of synapses on growing dendrites and their subsequent refinement by experience also occurs at a slower pace in frontal cortex than in sensory cortices. Whereas synaptic density peaks at 3 months of age in primary auditory and visual cortices, it peaks at 3.5 years of age in frontal cortex. It is widely held that experience sculpts cortical circuitry largely by stabilizing some synapses while eliminating others. This process of synaptic elimination is complete by 12 years of age in primary sensory cortices, but is more gradual in frontal cortex, continuing

throughout mid-adolescence (Huttenlocher and Dabholkar 1997). Myelination of subcortical white matter is perhaps most prolonged, continuing into the second decade of life (Giedd et al. 1999; Klingberg et al. 1999).

The slow, progressive growth and refinement of this cortical circuitry enables sensory experience to profoundly impact the final structure and function of frontal and temporal cortices. As discussed below, these processes are accelerated in autism, forcing a premature closure of critical periods for language and social learning.

Pathophysiology

Development of Frontal and Temporal Cortex in Autism

There are no postmortem studies of neural anatomy in autistic children ages 2–4, the typical age of diagnosis. Thus, we do not know how the fine structure of neurons and refinements in synapse number and connectivity are impacted by autism. However, a growing number of brain imaging studies indicate that gray matter in frontal and temporal cortices grows precociously in the autistic brain. At the earliest ages measured, 2.5 years of age, the thickness of frontal and temporal gray matter is already 6% and 9% greater, respectively, than typical, and this accelerated growth continues through at least 5 years of age (Schumann et al. 2010). Despite this early overgrowth, there is some evidence that it is short lived – frontal and temporal gray matter increase by only 1% between ages 6 and 8 in autistic children during which time the normally developing brain experiences increases of 17–20% (Carper et al. 2002). Thus, frontal and temporal gray matter thickness increases rapidly in the autistic brain, reaching adult thickness a decade or more ahead of normal pace. The precocious overgrowth of the autistic brain is perhaps most apparent when noting that the average brain weight in 3–5-year-old autistic children is equivalent to that of normal adults (Courchesne et al. 1999). The normally slow growth of cortical gray matter parallels the emergence and slow acquisition of language and social skills. The premature cessation of cortical growth

in autism would almost certainly impair their refinement.

Synaptic density measurements support a view of premature closure of critical periods. The density of dendritic spines – the postsynaptic specializations of dendrites that receive excitatory inputs – is increased in autism (Hutsler and Zhang 2010; van Spronsen and Hoogenraad 2010), suggesting an absence of the normal pruning processes necessary for the refinement of circuit function.

How the signaling pathways that drive autism impact the structure and function of individual neurons and their synapses can only be achieved by studying mouse models of autism. We discuss recent advances in this line of investigation below.

Synaptic Plasticity in Mice Carrying Mutations in Autism-Candidate Genes

The maturation of appropriate cortical connectivity and function depends on long-term changes in synaptic strength. These changes include enhancements in synaptic strength (long-term potentiation; LTP) and reductions in synaptic strength (long-term depression; LTD), as well as the formation of new synapses and the retraction of others. It is conceivable that abnormal synaptic plasticity could contribute to deficits in circuit refinement and behavioral inflexibility seen in autistic patients. To discover whether alterations in synaptic plasticity play a role in the cognitive and behavioral deficits suffered by patients with autism, studies of cortical and hippocampal LTP and LTD have been performed in a number of mouse models with deletions of autism-related genes; these studies are summarized in Table 1. Additionally, recent advances in nonlinear microscopy permit longitudinal imaging studies of synaptic structure in vivo in mouse models of autism.

Altered Synaptic Strengthening

Mice engineered to have the R451C neuroligin-3 mutation found in a small number of patients with autism, have social behavioral deficits and enhanced learning (Tabuchi et al. 2007; Etherton et al. 2011). They have enhanced inhibitory transmission in the cortex, and enhanced excitatory transmission in the hippocampus (Etherton et al.).

Plasticity, Neural, Table 1 Autism related genes and neural plasticity

Gene	Protein function	Syndrome	Synaptic plasticity/ function	Learning deficits	Molecular features
<i>CACNA1C</i>	Calcium channel	Timothy syndrome	Impaired Schaffer collateral late LTP	Impaired hippocampal spatial memory	
<i>CNTNAP2</i>	Cell adhesion molecule	Autism/epilepsy/MR	—	Differential expression in bird song learning nuclei	Clusters potassium channels
<i>CYFIP1</i>	Synaptic translation regulation	Autism	—	—	Binds and regulates FMR1
<i>DISC1</i>		Autism/Schizophrenia	Impaired hippocampal short term plasticity; short dendrites; decreased spine density	Abnormal spatial working memory	Controls Rac1 activation by NMDA receptors
<i>FMR1</i>	Activity-dependent synaptic translation regulation	Fragile X syndrome	Increased mGluR dependent LTD; impaired LTP in the prefrontal and visual cortex. Decreased spine stability; reduced experience-dependent changes in spine stability	Impaired hippocampal spatial memory. Altered ocular dominance plasticity	
<i>NGLUT3</i>	Glucose transporter	Autism		Abnormal spatial and working memory	
				Cognitive inflexibility	
<i>Neurologin3</i>	Synaptic adhesion molecule	Autism/MR	Increased cortical inhibition; Increased hippocampal excitation. Increased hippocampal LTP	Improved spatial memory	
				Social Social behavior deficit	
<i>MECP2</i>	Transcriptional regulator	Rett Syndrome	Impaired cortical and hippocampal LTP. Impaired hippocampal LTD	Impaired Hippocampus-dependent spatial memory, contextual fear memory, and social behavior	Binds methylated cytosine to regulate activity dependent transcription
<i>PTEN</i>	Cell/dendritic growth regulator	Autism/MR; Cowden syndrome; or Bannayan-Riley-Ruvalcaba syndrome	Impaired hippocampal LTD; increased dendritic growth, decreased spine stability; increased spine density	Social behavior deficits	Inhibits activation of mTOR pathway
<i>TSC1</i>	Cell growth	Tuberous sclerosis	decreased spine density; increased AMPAR currents	Impaired hippocampal spatial memory	Inhibits activation of mTOR pathway

(continued)

Plasticity, Neural, Table 1 (continued)

Gene	Protein function	Syndrome	Synaptic plasticity/ function	Learning deficits	Molecular features
<i>TSC2</i>	Cell growth	Tuberous sclerosis	Abnormal induction of hippocampal Late-LTP; decreased spine density	Impaired hippocampal learning behavior	Inhibits activation of mTOR pathway
<i>UBE3a</i>	Proteosomal regulator	Autism; Angelman syndrome	Impaired visual cortical LTD; decreased spine density	Impaired ocular dominance plasticity	E3 ubiquitin ligase
<i>Shank3</i>	Synaptic adhesion molecule	Autism	Impaired hippocampal NMDAR LTP, LTD. Enhanced mGluR dependent LTD	Social behavioral deficits	

In addition, they show enhanced hippocampal LTP, likely because of an upregulation of the NMDA receptor NR2B subunit (Etherton et al.).

Mice with Shank3 C-terminus truncation mimicking the human autism-related mutation have loss of Shank3 at synapses. These mice have social behavioral deficits, loss of NMDA receptors at synapses, and loss of NMDAR dependent LTP (Bangash et al. 2011).

Deletion of CACNA1C, encoding a calcium channel mutated in Timothy Syndrome, an autistic spectrum syndrome, results in deficient Schaffer Collateral Late-LTP in the hippocampus (Moosmang et al. 2005). Deletion of MECP2, encoding a chromatin binding protein mutated in Rett Syndrome, another autism spectrum disorder, also results in deficient hippocampal (and cortical) LTP (Moretti et al. 2006; Weng et al. 2011). Conversely, loss of activity induced phosphorylation of MECP2 results in enhanced binding of MECP2 to target promoters, results in enhanced hippocampal LTP, and enhanced learning in hippocampal-dependent tasks (Li et al. 2011). Deletion of FMR1, the gene implicated in Fragile X syndrome, results in decreased LTP in the visual cortex (Wilson and Cox 2007), and loss of spike-timing dependent LTP in the prefrontal cortex (Meredith et al. 2007), but enhanced hetero-synaptic LTP in the hippocampus (Connor et al. 2011). Conversely, mice with deletions in TSC2, a gene mutated in the autism-related syndrome, tuberous sclerosis, show abnormal induction of late-LTP by stimuli that only induce early-LTP in control mice (Ehninger et al. 2008).

Altered Synaptic Weakening

MECP2 knockout mice (Moretti et al. 2006), as well as mice with conditional deletion of PTEN, a regulator of the mTOR pathway that is mutated in a significant cohort of patients with autism and extreme macrocephaly, show impaired hippocampal LTD (Jurado et al. 2010). PTEN conditional knockout mice show dramatic social behavioral deficits as well as seizures. Mice with deletions of UBE3a, an E3 ubiquitin ligase, implicated in the autism-related Angelman syndrome show impaired LTD in visual cortex (Yashiro et al. 2009). Consistent with a role of LTD in experience-dependent plasticity in the cortex, these mice show impaired ocular dominance plasticity when challenged with monocular deprivation (Yashiro et al.). In contrast to the above models, mice with deletions of FMR1, the gene implicated in Fragile X syndrome as well as Shank3 mutant mice have *increased* mGluR-dependent LTD in the hippocampus (Huber et al. 2002; Hou et al. 2006). FMR1 mice also show abnormal visual cortical plasticity (Dolen et al. 2007) and both FMR1 and Shank3 mice show impairments on a number of spatial and social behaviors (Bangash et al. 2011; Krueger et al. 2011).

Deficits in Synapse Number

Changes in the total number of synapses made onto single neurons can profoundly impact the firing properties of these cells and alter network function. In cultured neurons, loss of TSC1 or TSC2 decreases the density of dendritic spines,

the morphological correlates of synaptic contacts. Decreases in cortical spine density are also observed following loss of UBE3a (Dindot et al. 2008; Sato and Stryker 2010) or DISC1 point mutation (Lee et al. 2011) in vivo. Notably, spine density is not affected by mutations of MET, a receptor upstream of the AKT signaling pathway. Taken together these observations suggest that either the normal establishment of spines is impaired or that their subsequent stabilization is compromised. Recent in vivo longitudinal imaging studies, presented below, support the latter view.

Deficits in Synaptic Stability

In addition to impairments in synaptic strength, a growing body of research implicates deficits in the physical growth and elimination of synapses in autism. Recent advances in nonlinear microscopy have enabled investigations of synaptic stability in wild-type and mutant mice. Using 2-photon excitation, the fine structure of individual neurons, their dendrites, and the spines emerging from these dendrites can be visualized in vivo. Dendritic spines are the postsynaptic element of excitatory synapses, and thus each spine represents a single synapse. Because this approach does not damage the imaged cortex, these same neurons, dendrites, and dendritic spines can be reimaged daily or weekly and the fates of individual spines followed for months. This approach has been used to longitudinally image dendrites and dendritic spines in mice with mutations in Pten and FMR1. In both mutants, the lifetimes of spines are reduced, indicating that cortical connectivity is far more kinetic and thus less stable. Notably, spine stability was less sensitive to changes in experience in FMR1 mutant mice. These observations suggest that the refinement of synaptic connections that is the hallmark of the critical period cortex is driven more by intrinsic activity patterns than by sensory experience.

Conclusion

Changes in neural structure, synaptic strength, and synaptic density occur throughout life but

are most pronounced after the onset of sensory experience. Observations from mice harboring mutations of autism-candidate genes indicate that synapse number and stability are reduced and changes in their strength and stability are less sensitive to the pattern of neural activity. Impairments in use-dependent synaptic plasticity would severely impact the final structure and function of neural circuitry in all areas of the brain, but particularly so in cortex. Recent evidence showing that autism-like behaviors can be induced by altering the balance of excitation and inhibition in cortex in adult mice or by manipulating autism-candidate genes in adult mice supports a view of the disease in which postnatal plasticity, rather than initial patterning, is a prime driver of abnormal social behavior in autistic individuals.

Definition

Play is a difficult phenomenon to define. Many theorists have attempted to develop strict definitions of play, but it is an occurrence which eludes simple definition (Pelligrini 2009). Because play differs so dramatically across individuals, contexts, and cultures, there currently exist lists of characteristics often indicative of play situations, rather than a strict definition itself. For example, play may be distinguished in terms of functional dimensions, in that it often does not have a functional or goal-directed consequence (e.g., play fighting does not hurt others), and it is often more oriented toward means than ends. In addition, play may be distinguished in causal dimensions, in that play will

frequently be interrupted by more pressing, functional concerns, players exhibit relaxed motivation (i.e. play is voluntary), and play is often characteristic of juveniles (i.e. children play more frequently than adults). Because there is not a universally-accepted definition of play, researchers apply different descriptions of play characteristics to identify play in different contexts. Nevertheless, such characteristics converge toward a definition of a complex phenomenon.

Historical Background

Two developmentalists have had extraordinary influence in defining play and its development. Parten (1932) focused on social participation within play, and Piaget (1952) focused on the development of object play as a reflection of developing cognitive processes. Prior to the 1930s, only “scattered individual attempts” (Parten 1932, p. 246) had been made to study children’s social behavior more generally and play more specifically. Mildred Parten, at the University of Minnesota, recognized the need for systematic study of child group behavior. She pioneered the longitudinal observational study of children’s social behavior within the nursery school of the Institute of Child Welfare at the University of Minnesota. Results from this study formed the basis of categorization of types of children’s play.

Parten (1932) observed 42 children across 8 months’ time. Although children’s IQ ranged from 81 to 145, the mean IQ indicated above-average mental ability, and a high percentage of children had fathers with professional careers. Generalization of research results drawn from such studies, as well as considerations of cross-cultural studies of play, is discussed below. After several weeks of careful observation, Parten (1932) developed a scale of social participation within play. The following stages represent increasingly socialized forms of play:

1. Unoccupied behavior: The child does not seem to be playing but instead occupies him/herself with watching anything that happens to be of

momentary interest. When nothing external interests him/her; he/she plays with his/her own body, gets on and off chairs, stands or sits unoccupied, or follows the teacher.

2. Onlooker: The child observes a group of children playing but does not overtly enter into the play activity. The child may, however, talk to the children whom he/she is observing, ask questions, or give suggestions.
3. Solitary independent play: The child plays alone and independently with toys different from those used by nearby children. He/she makes no effort to get close to other children or to reference what others are doing.
4. Parallel activity: The child plays beside, rather than with, other children. The activity that he chooses naturally brings him/her close to other children, but he/she plays independently. Toys used are similar to those used by others around him/her, but he/she plays with them as he/she desires and does not try to influence the activity of the other children.
5. Associative play: The child plays with other children. In this group play, there is an overt recognition by the group members of their common activity, interests, and personal associations. Although all group members engage in similar or identical activity, there is no division of labor and no organization of the activity around any material goal or product.
6. Cooperative or organized supplementary play: The child plays in a group that is organized for the purpose of making some material product, attaining some competitive goal, dramatizing situations of adult or group life, or playing formal games. This represents the most highly organized group activity and is marked by elements of division of labor, group censorship, centralization of control in the hands of one or two members, and the subordination of individual desire to that of the group.

Parten's observational study involved 2–4-year-olds, and she found a clear progression through stages of play as children aged. The younger children either played alone or in parallel groups, while the older children played in the more highly organized groups. Parten's play

categories are still respected and widely used as a meaningful framework within which to examine children's increasing maturity of play.

Piaget provided the first detailed theory of play development from a cognitive perspective. Although many writers prior to Piaget theorized that play was important to children's development, Piaget elaborated upon play's significance in terms of cognitive development and defined three types of play. Like Parten (1932), Piaget (1952) theorized that these categories of play were organized into stages which children move through as they develop. According to Piaget (1952), children move through three primary ordered stages during their first four years of life. His theory, like that of Parten (1932) two decades prior, has remained highly influential. Piaget suggested that children's play moves from motor actions to underlying cognitive representation over time. Piaget (1952) outlined the following three stages:

1. Practice play: Characteristic of children from approximately 2 months to 2 years of age. During this stage, children are not yet motivated or influenced by convention, symbols, pretending, or rules. Instead, they utilize sensorimotor activities to gain pleasure – mastery motivation – based on agency, via moving their bodies or objects and repeating learned actions. Infants in this stage develop the ability to combine different sensorimotor action schemes in their practice play, begin to define objects by their use, and perform ritualistic action patterns in which typical actions with conventional objects are performed. However, the play in this stage is limited in that infants will not apply these actions to new objects or display an awareness of make-believe.
2. Symbolic play: Characteristic of children from approximately 2–4 years of age. During this stage, children make the transition from sensorimotor schemes to mental operations or representations. Piaget (1952) detailed eight ordinal levels of symbolic play, leading from the earliest forms involving the use of familiar actions on novel objects (e.g., putting a box on the foot and saying it is a shoe) to the reproduction of

scenes from reality, corrected to “fix” certain outcomes (e.g., after a recent trip to the doctor, the child might pretend that doctor did not give him/her a shot, but instead gave him/her a lollipop).

3. Games with rules: Characteristic of children from approximately 4–7 years of age. During this stage, children become interested in social games involving rules, structure, and social interaction. Over time, the types of rules, as well as the reasons for following them change. Children at first follow rules centered on the sensorimotor aspects of play which provide structure and repetition. Later, rules become focused on the social aspects of play and are connected to group acceptance. Finally, competitive games and games with codes of rules become more frequently played.

The theories described above can easily be combined to imagine a typical child’s progression through play development both in social interaction and cognition. A 2-year-old child might, for example, engage in parallel play while projecting symbolic schemes onto new objects, while a 4-year-old child might engage in cooperative supplemental play while exploring anticipatory combinations. For all the research on play that has occurred since Parten (1932) and Piaget (1952), their research and theories continue to influence current play research.

Current Knowledge

Play, in its various forms and stages, affects children’s development widely (Bjorklund 1997). Many theorists argue, in fact, that it is primarily through play that children’s cognition develops (Dansky 1980; Piaget 1952). Play can be viewed from an evolutionary perspective as a mechanism by which children master skills that will be important for their survival and development to maturity (Bruner 1972). According to Bjorklund (1997), the play exhibited by children has an adaptive role in both evolution and human development. He argues that the play exhibited by children in humans’ protracted period of immaturity is a

necessary component of development and leads to successful learning by children of the complexity and diversity of contemporary human community. Play is a forum through which children develop skills and knowledge related to motor skills, culturally acceptable social behaviors (Bruner 1972), spatial and classification skills (Connolly and Doyle 1984), language fluency, abstract thought and intelligence (Weininger 1978), and innovative problem-solving (Smith and Dutton 1979).

Many categories of play cited today correspond to the stages of play development outlined by Parten (1932) and Piaget (1952). Categories of play include:

- Sensorimotor or exploratory play: This is also known as practice play and corresponds to the first stage of Piaget’s (1952) theory outlining development of play. In sensorimotor play, children manipulate objects as a means for practice and mastery of action schemas. Sensorimotor play involves repetition of behaviors, routines, and subroutines that have been mastered. Examples include infants’ rhythmic motor behaviors, such as repetitive kicking or shaking of an object (Pelligrini 2009; Rogers et al. 2005).
- Functional play: Functional play is categorized in one of two ways. According to some researchers, functional play is a synonym for the sensorimotor or practice play described above (Pelligrini 2009). For others, it is a separate category of play involving the child combining objects and forming play acts in ways that reflect social conventions. In this category of play, children use objects in the ways that they are typically used. Examples include a child eating and drinking from play dishes and placing a toy cup on a saucer (Rogers et al. 2005).
- Pretend play: Also called symbolic play, fantasy play, or make-believe play, this corresponds to the second stage of Piaget’s (1952) theory outlining the development of play. Pretend play is a primarily assimilative behavior where in the child takes a behavior out of its functional context or recombines everyday behavioral sequences in novel orders

(Pelligrini 2009). In pretend play, absent elements are often represented through objects, gestures, and language. It grows out of the child's developing ability for mental representation and provides a means for practicing and gaining understanding of the events of the social world (Rogers et al. 2005). Examples include a child utilizing a stick in place of a spoon to stir pretend liquid in a cup or pretending that one is a train conductor.

- **Games with rules:** This type of play corresponds to the third stage of Piaget's (1952) theory outlining the development of play. In this type of play, games are primarily accommodative and governed by a priori rules. Although there is some negotiation in the rules of children's games, these rules are generally not flexible (Pelligrini 2009). Examples include baseball and board games.
- **Parallel play:** This type of play corresponds to the fourth stage of Parten's (1932) theory outlining the development of play. In this type of play, the child plays beside, rather than with, other children. Although the child uses similar toys as those around him, he/she plays with them independently and as he/she desires, and he/she makes no effort to influence the play of others. Examples include playing with dump trucks in a sandbox or playing with toy boats in a water table, next to other children playing similar games.
- **Social play:** This type of play corresponds to the fifth and sixth stages of Parten's (1932) theory outlining the development of play (associative play and cooperative play). Here, the child plays with other children. As evidenced by the multiple corresponding stages, there is a continuum of social play. As in cooperative play, the group of playing children may organize itself in order to make some material product, attain some competitive goal, dramatize situations of adult or group life, or play formal games. As in associative play, the children may merely play with one another, with an overt recognition by the members of their common activity, interests, and personal associations but without division of labor or organization.

- **Exploratory play:** It has been argued that exploration is a separate activity than play. Some researchers argue that exploratory behaviors occur prior to play behaviors in the first few months of life. They note that exploration is performed in a deliberate manner, often in novel contexts, in order to gather information, while play is exhibited in familiar contexts with positive affect in order to practice (Pelligrini 2009). Other researchers, however, view exploration as a type of play and hypothesize that children learn cause and effect relationships through such play (Schultz and Bonawitz 2007). Piaget himself argued that children construct knowledge via active exploration (Piaget 1930), and exploratory play is believed to accomplish such knowledge attainment. Examples of exploratory play include mouthing objects and dropping objects to observe what happens.

Cultural Influences on Play

Roopnarine, Johnson, and Hooper (1994) describe cultural-ecological models of behavior and stress the importance of applying such models to research of play. According to a cultural-ecological model, there are three interacting layers of environmental influence on play: (1) physical and social aspects of children's immediate settings; (2) historical influences that affect the way adults and children conceptualize play; and (3) cultural and ideological beliefs regarding the meaning of play. A wide range of variables contribute to the development, significance, and value of play and are highly influenced by ecological context at many levels. Play is an expression of a particular culture and an important context for transmission of that culture (Schwartzman 1978). Although some research has been conducted on the cross-cultural development of play, the majority of taxonomies of play forms, as well as discussions of the significance and value of play, have been based on studies of Western children and have made global assumptions. In order to achieve a more comprehensive, coherent, and integrated knowledge base of play, it is necessary to expand these cross-cultural considerations in future play research (Roopnarine et al. 1994).

Play in Autism

Many studies have repeatedly isolated symbolic play deficits as a core feature of autism. In Ricks and Wing 1975, for example, Ricks and Wing reviewed what was known about autism up to that point and concluded that a central deficit within children diagnosed with autism is the inability to understand symbols. This inability affected, among other areas, the symbolic play skills of children with autism. Expanding on that paper, Wing, Gould, Yeates, and Brierley (1977) published the first major research paper on symbolic play in autism. They confirmed that in children with autism, there is a lack of spontaneous symbolic play, and that for those who did demonstrate some amount of symbolic play, the play acts were repetitive and stereotypic. Children with autism do not perform symbolic play acts as frequently as other children, and when they do perform these play acts, the play lacks variety.

Additional research has replicated these original findings and strengthened the viewpoint that children with autism engage in fewer and poorer quality symbolic play acts (Hammes and Langdell 1981; Riguette et al. 1981). Sigman and colleagues (Mundy et al. 1986; Sigman and Ungerer 1984) replicated these findings but also found that non-symbolic play was affected in children with autism.

Although Sigman and colleagues (Mundy et al. 1986; Sigman and Ungerer 1984) found that children with autism exhibit a paucity of functional and sensorimotor play skills in addition to exhibiting a lack of symbolic play skills, evidence on this has been mixed. While Baron-Cohen (1987) and Sigman and Ruskin (1999) found no deficits in functional play skills in children with autism, the majority of studies have found differences in functional and sensorimotor play skills in children with autism as compared to matched comparison groups. For example, Sigman and Ungerer (1984) reported that in spontaneous play conditions, young children with autism produced fewer functional play acts, fewer different functional play acts, and fewer sequences than intellectually disabled children in their comparison group. In addition, Williams, Reddy, and Costall (2001) found deficits in both functional

and sensorimotor play in children with autism. These children exhibited lower rates of both types of play acts and performed more immature than mature play acts. The research across the symbolic, functional, and sensorimotor play skills in children with autism demonstrates similar patterns of findings: children with autism exhibit fewer play acts, more repetition, less novelty, and less diversity of play schemas.

Interventions have been demonstrated to improve the play skills of children with autism. Direct teaching and naturalistic teaching approaches have demonstrated significant effects on children's play (Kasari et al. 2006, 2008; Kasari et al. 2008; Reddy et al. 2005; Rogers 2005), addressing both functional and symbolic play deficits. Targeting play for interventions serves to increase children's play as a learning tool and also provides older children with appropriate recreational activities.

Future Directions

Future needs related to autism play research fall under two primary areas: brain behavior correlates and effects of play skills on later development. Neuroscience has not yet been incorporated into models or studies of play (Rogers et al. 2005). Play is a cognitive activity as well as a motor and social-emotional activity. Observers can distinguish between adaptive acts and play acts in children's behavior, with the assumption that some differing neural processes are involved, even when the overt act is the same. It will be helpful for researchers to begin to consider the neural systems underlying play and the neuropsychology of play. Play is considered an important therapeutic medium for a number of childhood disorders (Reddy et al. 2005). Most childhood interventions for autism spectrum disorder target play skills, without much knowledge about the relationships between childhood play skills and their effects on later development. Longitudinal research in this area is sorely needed. Expanding the multilevel accounts of play should assist future researchers to understand the change process facilitated by play, both developmentally and therapeutically.

Play Intervention

Brooke Ingersoll and Katherine Walton
Department of Psychology, Michigan State
University, East Lansing, MI, USA

Definition

Play intervention is a term used to describe psychosocial interventions designed to improve play skills in children with ASD. The term has also been used to describe interventions that take place within a play setting, but focus instead on increasing social or language skills. This entry will focus on intervention developed specifically to target play skills in children with ASD.

Play is a broad term that describes a variety of skills, including object-oriented play, pretense, and play with peers. Children with ASD have significant deficits in all of these areas, and a lack of varied, spontaneous make-believe play or social imitative play is a hallmark feature of the disorder (American Psychiatric Association [APA] 2000). Thus, a variety of intervention strategies have been developed to target play skills in children with ASD, including discrete trial training (DTT), naturalistic behavioral interventions, integrated play groups, video modeling, differential reinforcement of appropriate behavior (DRA), self-management, and play scripts (see Stahmer et al. 2003 for review).

The term “play intervention” is most commonly used to describe a group of naturalistic intervention techniques that take place in a play setting, and may or may not involve typically developing peers. As such, this entry is focused on play intervention of this type. Within a play setting, the intervention provider uses a number of techniques to engage the child with the materials and with the provider (e.g., following along with the child’s focus of interest, acting excited and animated about the child’s play). With the child engaged in the interaction, the intervention provider then provides models and prompts (either verbal or physical) to encourage the child to complete more complex or advanced play actions than he is currently using. When the child responds by completing the prompted play actions, the intervention provider typically praises the child verbally and rewards the child by allowing him continued access to the toys.

Historical Background

Limited and perseverative play has been described as a difficulty for children with autism since Kanner’s first description of the syndrome in 1943. More systematic research as early as 1964 indicates that, compared to typically developing or intellectually disabled children, children with autism show more stereotyped play, less diversity of play, and less symbolic play (Wulff 1985). When autism first appeared in the third edition

of the Diagnostic and Statistical Manual of Mental Disorders in 1980, difficulty with imaginative play and social play were included as symptoms of the disorder. The first treatment to specifically target play skills in children with autism and other developmental delays was discrete trial training. However, given concerns about generalization of skills and appropriateness of such structured programs for young children, most play interventions now take place in a more naturalistic setting. Pivotal response training (PRT), a naturalistic behavioral intervention originally designed to teach language to children with autism, was the first intervention of its type to be successfully adapted to teach symbolic play skills to children with autism (Stahmer 1995). Since this time, a number of other naturalistic behavioral interventions have been used to teach play as well.

Rationale or Underlying Theory

The play deficits (particularly regarding symbolic play) seen in children with autism have been theoretically linked to difficulties with symbol formation more generally. Other skills that rely heavily on symbol formation are language and abstract reasoning (Wulff 1985). In addition, play is seen as a fundamental way in which young children connect socially, both with adults and with other children (e.g., Mueller and Brenner 1977). Therefore, interventions that improve symbolic play skills in children with autism may also have collateral effects on language, cognitive skills, and social skills. Early toy play skills are associated with later communication development (Toth et al. 2006). In addition, children receiving play intervention have shown increases in other skills not specifically targeted in these interventions, such as language, joint attention, and interaction skills (Stahmer et al. 2003).

Goals and Objectives

Play intervention is designed to target a variety of object-interaction and social play skills. For children who interact little with objects or engage

primarily in stereotyped play, play intervention targets are likely to be simple meaningful toy interactions, such as combining toys in a meaningful manner (e.g., stacking blocks). This type of simple relational play is seen as a necessary precursor to more complex symbolic or pretend play (van Berckelaer-Onnes 2003), and increases in appropriate play are associated with decreases in less-meaningful stereotyped play (Stahmer and Schreibman 1992). For children with more advanced play skills or who are further into a play intervention treatment program, more complex actions and play schemes such as doll play, multiple-step pretend schemes, and sociodramatic play with a partner are likely to be targeted.

Treatment Participants

Play intervention has primarily been targeted at relatively young children (approximately 2–6 years of age). Some research has indicated that play intervention is likely to be more successful for children with higher IQ's (Wulff 1985) and higher initial object-interaction skills (Ingersoll 2010).

Treatment Procedures

Play intervention is typically carried out in a play-based setting, with a number of toys available to the child and therapist. Structure of the sessions may vary depending on the specific approach used, but most play interventions include at least a portion of the session that provides opportunities for teaching within a semi-structured play setting. More structured approaches, such as pivotal response training, may include table-top drills to teach new skills during a portion of the session. Less structured approaches, such as incidental teaching, are more child-directed and rely heavily on teaching around the child's chosen focus of interest. Sessions are usually conducted two to seven times per week for 30–60 min. Major tenets of play intervention include the use of techniques to engage the child in interaction (e.g., following the child's lead, talking about what the child is

doing, sitting close to the child) and the use of modeling, prompting, and reinforcement strategies (e.g., telling or showing the child what to do, giving verbal praise for correct responses, providing corrective feedback, rewarding the child's correct responses with continued access to toys). Play intervention has been successful in a number of treatment formats, including therapist-, parent-, peer-, and sibling-implemented models (Stahmer et al. 2003).

Efficacy Information

Play intervention has been successful at teaching functional and symbolic play skills for children with autism (Kasari et al. 2006). In many cases, collateral benefits on other skills, such as language and social skills, have also been observed (Kasari et al. 2008). These skill improvements have been found to persist up to 1 year later. Increases in both spontaneous and prompted play skills have been observed in nontreatment settings (e.g., standardized assessments, parent-child play sessions) following play intervention. However, generalization of these skills to settings with typically developing peers has not been evident, suggesting that peer play may need to be targeted explicitly. In addition, the play of children with autism often remains qualitatively different from that of typically developing children even following play intervention (Stahmer et al. 2006).

Outcome Measurement

Researchers have measured play in a variety of ways, including total time spent playing with toys, time spent in appropriate play, diversity of object play, and play complexity or level. All of these elements of play have been found to significantly discriminate children with autism from those with typical development, intellectual disability, hearing impairment, and language impairment (Stone et al. 1990).

Several structured assessments have been used to assess treatment outcome and relationships between play skills and other skills in children

with autism. The Structured Play Assessment (SPA; Ungerer and Sigman 1981) provides children with four different sets of toys and a variety of structured play prompts designed to elicit play skills at a number of different play levels. Both prompted and spontaneous play acts are coded for play level: manipulative, relational, functional, or symbolic. Manipulative play consists of actions such as mouthing, banging, fingering, or throwing toys. Relational play consists of combining objects in nonfunctional ways (e.g., nesting or stacking objects). Functional play consists of using objects in a way they were intended, such as brushing a doll's hair, placing a truck in a garage, or holding a phone to one's ear. Symbolic play consists of object substitution (pretending one object is another), use of a doll as an independent agent, and imaginary play (creation of an object or effect that is not actually present). The SPA has been used by a number of researchers to measure treatment outcome and relationship among play skills and other social-communication skills in children with autism (Kasari et al. 2008; Sigman and Ungerer 1984; Ungerer and Sigman 1981).

The Developmental Play Assessment (DPA; Lifter et al. 1988) consists of a 30-min videotaped free play session with a child and an administrator. The administrator comments on the child's play, but does not provide prompts or instructions for play. Each play act on the videotape is later coded to determine what play category the act fits in to. Each play act is then placed into one of eight play categories (e.g., indiscriminate actions, child as agent, doll as agent, sociodramatic play) and the total number and diversity of acts in each category are tallied to determine whether the child has absent skills, emerging skills, or mastery in each category. Play categories were designated based upon numerous studies of the development of play skills in children with typical development and with disabilities. The DPA has been used as a measure of play skills in children with and without autism in number of research studies (Pierce-Jordan and Lifter 2005; Lifter et al. 1993; Yoder and Stone 2006).

Qualifications of Treatment Providers

Play intervention is provided by a wide range of treatment providers, including teachers, speech pathologists, psychologists, social workers, and physicians. In addition, family members and peers can be trained to serve as treatment providers or treatment aids in play intervention. A number of play intervention programs are accessible through training workshops or published materials.

PLAY Project

Richard Solomon

Ann Arbor Center for Developmental and Behavioral Pediatrics, Ann Arbor, MI, USA

Definition

The PLAY Project (PLAY) is a parent-implemented, intensive (10–15 h/week) early intervention program for young children (18 m–6 y) with autism spectrum disorders (ASD) that uses a developmental, relationship-based (DRB) framework. The goal of the PLAY Project Organization is to help as many families as possible engage in a joyful and effective way with their child to help their child reach key functional developmental milestones. To achieve this goal, a national network of certified PLAY Consultants provide monthly (2–3 h) or weekly (1 h) visits, coach and partner with families to build trust, promote family confidence and competence, and strengthen family-child relationships through playful engagement. PLAY uses videotape and written feedback to help families learn the manualized principles, methods, techniques, and activities of the model. Rigorous NIMH research on PLAY (Solomon et al. 2014) has shown that families gain the knowledge and skills needed to enrich their children's interactional and developmental abilities. As a result, children in the research study made social, emotional, and developmental progress. PLAY is one of the few evidence-based parent-implemented models to show a reduction in the child's autism symptomatology.

Historical Background

From 2000 to 2005, in response to the lack of autism early intervention services in Michigan, Richard Solomon MD, then section head of developmental and behavioral pediatrics at the

University of Michigan, introduced the PLAY Project's (PLAY) developmental, relationship-based model (see Rationale/Underlying Theory below) to the community. A pre-post pilot study of the first 75 families enrolled in PLAY was published in the journal *Autism* in 2007 and indicated that parents could be coached to interact successfully with their young child with autism in a way that promoted the child's social-emotional functioning (Solomon et al. 2007). Subsequently, from 2009 to 2012, the PLAY Project was funded by the National Institutes of Mental Health's (NIMH) Small Business Innovations Research (SBIR) grant to implement a large ($n = 128$) randomized controlled trial comparing the PLAY Project plus Community Standard Services (primarily preschool) to Community Standard Services alone. The research results, published in 2014 in the *Journal of Developmental and Behavioral Pediatrics*, confirmed and extended the findings of the pilot study (Solomon et al. 2014). PLAY parents were successfully coached by PLAY Consultants to be more sensitive to, responsive to, and effective in interacting with their child with autism than control parents. Compared to control children, PLAY children improved in their interaction, compliance, initiation, and functional emotional development. PLAY children showed less autism symptomatology on the ADOS (Autism Diagnostic Observation Scale) than control children. PLAY parents were *not* more stressed for being asked to put in the time of PLAY (1–2 h/day) and, as a group, become less depressed over the year of intervention. After establishing its clinical and research foundations, PLAY has been broadly disseminated in dozens of states. In 2011, PLAY was implemented statewide by Ohio's Department of Developmental Disabilities in their early intervention (birth to 3) program for children with or at risk for ASD and now provides PLAY to over 70% of Ohio counties at no cost to families.

Rationale or Underlying Theory

The PLAY Project uses a parent-implemented model (PIM) to provide a developmental,

relationship-based (DRB) intervention for young children with autism spectrum disorders (ASD).

The theoretical foundations of DRB intervention date back to the 1950s and derive from the fields of psychology, medicine, and education. Bowlby, Bruner, A. Freud, Piaget, Ainsworth, Mahler, Vygotsky, and others established the theoretical and clinical basis for a developmental, transactional approach to intervention that relies on responsive caregivers and affective interaction. A foundational premise of DRB interventions is that there is an inherent biological drive toward increasing complexity of interaction, communication, and social repertoires in children, including those with autism. Greenspan integrated a Piagetian cognitive developmental framework with the psychoanalytic perspective and created an overarching developmental model called DIR (developmental, individual-difference, relationship-based) (Greenspan 1992; Greenspan and Wieder 2005).

Greenspan and Wieder then applied the DIR model clinically to children with ASD, emphasizing that the needs of children with ASD must be addressed from a holistic rather than piecemeal approach, with a view toward internal psychological affective development. They observed that many children with ASD have the capacity for sense of self and advanced levels of psychological and cognitive growth. Since then, several well-done studies have confirmed the effectiveness of using the DRB framework for parent-implemented interventions (Binns and Oram-Cardy 2019; Sandbank et al. 2019; Smith and Iadarola 2015; Mercer 2015; Wong and Odom 2014; Siller et al. 2013, 2014; Green et al. 2010).

Most empirical studies on DRB interventions use parent-implemented models (PIM) with *methods* that are child directed and *strategies* that utilize natural play rather than structured teaching or operant conditioning. The emphasis in intervention is on the role of the child as an active learner in the context of dyadic relationships. In PIM, parents are coached to sensitively read the child's cues, respond to the child's intention, challenge the child to move forward developmentally, and playfully join with the child through co-regulated interactions. Over the

past 30 years, and especially in the last 10 years, rigorous research has been accumulating about the effectiveness of DRB interventions (aka also as developmental social-pragmatic (DSP)) and PIM by documenting measurable improvements in joint attention, social engagement, initiative, reciprocity, functional development, and symbolic thinking (Hyman et al. 2020; Binns and Oram-Cardy 2019; Smith and Iadarola 2015; Mercer 2015; Wong and Odom 2014; Siller et al. 2013, 2014; Green et al. 2010).

Goals and Objectives

The PLAY Project (PLAY) trains pediatric professionals and child development experts to help parents engage their child with ASD to help the child make functional social developmental gains. Parent-implemented models, such as PLAY, can reach thousands of families many of whom are not receiving necessary services (Mandell et al. 2016). Thus, PLAY has three overarching goals:

1. The training of PLAY Consultants to a high degree of fidelity.
 2. Through PLAY Consultation, effectively coach and support parents to help their child to address the core deficits of ASD.
 3. Develop a model that can be replicated with high fidelity and disseminated on a large scale to address the large unmet need of families in the USA who have a young child with ASD.
1. *The training of PLAY Consultants to a high degree of fidelity.*

Qualified pediatric professionals and child development experts (SLP, OTs, MEd, PhD, and MD) are trained by following a three-step approach:

- (a) Attending a 2-day PLAY workshop to learn the basics of the PLAY Project model
- (b) Completing a 6-week online course to learn how to complete video reviews and write-ups
- (c) Undergoing 12–18 months of supervision to assure clinical fidelity to the model

After taking the online course, *PLAY Consultants-in-Training* begin serving families while under supervision. Supervision involves submitting 15 online videos and write-ups based on their clinical caseload to PLAY Project supervisors. The supervisors then evaluate consultant write-ups according to the PLAY Project Fidelity Manual. As part of the NIMH-SBIR research study (Solomon et al. 2014), fidelity of the study's PLAY Consultants was assessed. Twenty percent of all PC videos and write-ups were reviewed by two supervisors who assessed each consultant using the PLAY Project's Consultant Training Fidelity Manual. Results showed that each of the consultants had high fidelity to the model.

2. *Through PLAY Consultation, effectively coach and support parents to help their child to address the core deficits of ASD.*

The Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (DSM-5), is widely considered to be the universal authority for psychiatric diagnosis (APA 2013). At the core of the DSM 5's revised criteria for autism spectrum disorders (ASD) are "challenges in social communication and social interaction" including lack of "social-emotional reciprocity," "back and forth conversation," problems with "nonverbal/gestural communication," and difficulties with "imaginative play." Developmental, relationship-based interventions that use parent-implemented models are directed primarily at these core deficits described in the DSM 5, making them especially appropriate for young children with ASD. The NIMH-SBIR research confirmed that parents trained by PLAY Consultants improved in their ability to effectively engage their child with ASD and PLAY children improved in their functional development and social interactions.

In terms of supporting parents, mothers of children with ASD are reported to experience higher levels of depression than either mothers of typically developing children or mothers of children with other disabilities (e.g., Abbeduto et al. 2004; Singer 2006). A longitudinal study of 143 mothers of toddlers with confirmed

diagnoses of autism (Carter et al. 2009) reported that 35% of these mothers displayed clinical levels of depression symptoms when their children were less than 3 years of age, and 42% displayed clinical depression symptoms 2 years later. Parent-implemented models that offer social support to families, build family competence, and help family members engage their often hard-to-engage children make PIM especially appropriate for this population of young children with ASD. One of the unexpected outcomes of the NIMH-SBIR research on PLAY showed that parental depression of those who received the PLAY Project intervention declined significantly over the year of the study.

3. *Develop a public service model that can be replicated with high fidelity and disseminated on a large scale to address the large unmet need of families in the USA who have a young child with ASD.*

With the marked increase in the prevalence of autism (1 in 59) and the need to provide intensive early intervention for this growing number of children, too many children in the USA are not getting the services they need (Mandell et al. 2016). As part of its vision, the PLAY Project Organization (PPO) is dedicated to reaching as many families as possible. Parent-implemented models are much less costly than therapist delivered services and can be disseminated effectively on a large scale.

In 2011, the PLAY Project Organization was invited by the state of Ohio's Department of Developmental Disabilities to train early intervention workers across the state. Over the next 3 years, nearly 150 early intervention (birth to 3) providers were trained to certification. Currently, over 70% of the counties in Ohio offer PLAY. Families whose children have been diagnosed with ASD or who have "red flags" for ASD are offered PLAY services at no cost. A full evaluation of the implementation of PLAY services in Ohio was conducted independently by Marilyn Espe-Sherwindt PhD and her study group at Akron Children's Hospital ([https://www.](https://www.playproject.org/assets/PLAY-Evaluation-Final-Report.pdf)

[playproject.org/assets/PLAY-Evaluation-Final-Report.pdf](https://www.playproject.org/assets/PLAY-Evaluation-Final-Report.pdf)).

Treatment Procedures

Since 2001, the PLAY Project's (PLAY) training and certification program has trained hundreds of masters-/doctoral-level consultants (SLP, OTs, MEd, PhD, and MD), reaching thousands of children nationally with dissemination in dozens of states and several countries. PLAY typically supplements existing services (e.g., special education, language and occupational therapies, and/or applied behavioral analysis/behavioral interventions) but has been implemented as a primary intervention for ASD in early intervention settings.

PLAY services – provided by certified PLAY Consultants – can be delivered in the home or in the clinic setting. Home visits range from a single 2–3-h home visit monthly to hourly weekly visits (e.g., in early intervention (birth to 3) settings). PLAY services last from 1 to 3 years depending on the needs of the child and family. One week before the first visit, parents are encouraged to review PLAY's "Welcome to the PLAY Project" online course, PLAY Parent's Manual, and book recommendations. The online course introduces parents to PLAY principles, methods, activities, and techniques through e-learning methods combined with video examples. The PLAY Parent's Manual describes in detail the six functional developmental levels (FDLs) of Greenspan and Wieder's developmental, individual-difference, and relationship-based (DIR) theoretical framework and provides descriptions of dozens of PLAY techniques and activities based on the FDLs.

During the visits, the primary caregiver is targeted for instruction, but all caregivers are welcomed to attend PLAY coaching sessions. PLAY Consultants (PC) train parents through coaching, modeling, and video feedback. During *coaching*, PCs helped parents identify their child's subtle and hard-to-detect cues, respond contingently to the child's intentions, and effectively engage the child in reciprocal exchanges. Parents

are taught to provide appropriate developmental challenges to promote progress in the child's FDLs. During *modeling*, PCs play for 15–30 min with the child to demonstrate PLAY methods and techniques. During *video feedback*, the PC obtains a 10-min representative sample of parent play, and the parent obtains a 5-min representative sample of the consultant modeling. A written analysis of the video, sent between visits, reviews the parent-child and consultant-child video interactions, summarizes the child's developmental profile, and recommends methods and techniques. The program is revised to address the child's evolving developmental profile. For example, as children became easier to engage, the intervention emphasizes increasing the length of engagement, waiting for more initiation, and expecting more reciprocal social exchanges, thus increasing the complexity of interaction and helping the child move up FDLs. Typically PLAY Consultants are available between visits as needed by e-mail or phone. Families were encouraged to engage their child in 15- to 20-min play sessions and throughout daily for a total of 2 h/day of active engagement.

Parent support is a key element of PLAY services. PLAY Consultants are masters-level trained child development experts and are additionally trained through the certification process to be aware of the needs of families for referrals to social and/or mental health services. PCs partner with families to build trust, promote family confidence and competence, and strengthen family-child relationships through playful engagement.

Efficacy Information

Studies on the PLAY Project (PLAY) join a growing body of research literature on parent-implemented models that use a developmental, relationship-based framework (Binns and Oram-Cardy 2019). This literature has consistently found that parents are able to learn the methods of play-based interaction and, importantly, implement them in the natural environment of the home. Even in a single parent or two-working-

parent home, the parents spend over 40 h of waking time with their child who has ASD. Parents in PLAY's NIMH-SBIR study reported putting in an average of 11 h per week in active play sessions, without evidence of increased stress, and PLAY parents reported a reduction in depression over the 1 year of the intervention (Solomon et al. 2014). Family support was key factor contributing to the benefits of PLAY. When consultants coach well and parents learn well, then children with ASD do well. Treatment benefits for children in the PLAY studies showed clinically significant gains in engagement, purposeful activity, contingent reciprocal exchanges, and initiation. Functional emotional development improved. Gains in development and language for PLAY children were significant pre- to post-intervention but did not differ from the control group children. Autism symptoms as measured by the Autism Diagnostic Observation Scale (ADOS) markedly improved in the PLAY group versus controls. The NIMH-SBIR grant was implemented in five US cities, large (Detroit, MI) and small (Billings, MT), with a broad range of families in terms of SES, race, and family structure suggesting that PLAY was effective in diverse settings. Finally, for the last 9 years, PLAY has been disseminated statewide in early intervention (birth to 3) system with plans to implement statewide in Michigan and Illinois, suggesting that PLAY can be implemented effectively on a large scale.

Outcome Measurement

To measure the most important outcomes of parent-implemented models that use a developmental, relationship-based intervention (DRB) intervention, research questions must focus on the *interactional process*. Do parents interact with their child who has ASD better after learning DRB methods? Do the children subsequently interact better with their parents? Do the children show improvement in their functional development as a result? Only video analysis can validly provide these answers. We found that the Pivotal Behavior Rating Scale (PBRs) (Mahoney and Kim 2007) and

the Maternal Behavior Rating Scale (MBRS) (Mahoney et al. 1986) had valid and reliable psychometric properties. The Functional Emotional Assessment Scale (FEAS) (Greenspan et al. 2001) measured outcomes relevant to the PLAY Project's autism early intervention program. The Mullen Scales of Early Learning is a very good measure of overall development. For language, we used the MacArthur Communicative Developmental Inventory but its two-scale structure did not fit well with our ASD population. For models that make demands on families, stress measures like the Parenting Stress Index and a depression scale are indicated. We found the ADOS (Autism Diagnostic Observation Scale) and ADI-R measures to be very important in assessing autism symptomatology.

Qualifications of Treatment Providers

PLAY Consultants (PCs) must go through a rigorous training to become certified. Most PCs are masters level or better, licensed pediatric professionals (SLP, OT, MSW, psychologist, MD) or child development experts (EI providers, MEd) who are trained by following a three-step approach:

- (a) Attending a 2-day PLAY workshop to learn the basics of the PLAY Project model
- (b) Completing a 6-week online course to learn how to complete video reviews and write-ups
- (c) Undergoing 12–18 months of supervision to assure clinical fidelity to the model

After taking the online course, *PLAY Consultants-in-Training* may begin seeing families while under supervision. Supervision involves submitting 15 online videos and write-ups based on their clinical caseload to PLAY Project supervisors. The supervisors evaluate their write-ups according to the PLAY Project Fidelity Manual. Upon completion of supervision, consultants are then certified and licensed to use the PLAY Project model.

Play Space Design in Autism

Nicola Yuill

Children and Technology Lab, School of Psychology, University of Sussex, Brighton, UK

Definition: Play Space Design in Autism

Play is defined as behavior that is “freely chosen, personally directed and intrinsically motivated,” a definition drawn from Playwork Principles (PPSG 2005). It is a human right (UNCRC 1989), so it is incumbent on community facilities, notably schools and local authorities, to provide suitably designed spaces for children to be able to play. Play space design for children (and indeed adults) with autism has to involve consideration of what is “suitable” for the capacities and motivations of this group. This entry covers considerations of outdoor play space for primarily school-aged children. It does not cover play as in gaming and touches only briefly on virtual spaces.

Background

There is a long history of designing for children’s play, from the earliest construction of the first toys, objects specifically designed for children to play with, to the influence of the German movement of the nineteenth century to provide spaces for children to play off the street and the first purpose-built playground, built in Manchester, UK, in 1859 (ESPPLAY 2012). The evolution of design for special needs, and autism in particular, has been driven by changes in thinking about design more generally. Changes in the past decades include ideas about inclusive and universal design, consideration of separate or shared facilities, the importance of physical health and mental well-being, and the sometimes conflicting properties of “natural” play and forest schools vs. the use of technology to design virtual and augmented play spaces.

Current Knowledge

Development and Play

Play is deemed by psychologists to be a crucial part of children's development, with a special role in cognitive and social growth. Very generally, functional play (such as play with objects) helps children learn about physical properties of the world, causal relations, and how things work. Differences in object play have been reported in autism, and tangible toys are sometimes developed and recommended to support shared object play (e.g., Farr et al. 2010). Symbolic play involves using objects, actions, or ideas to stand for other such objects and in particular concerns pretend play. Pretend play is marked as being delayed or different in autism (REF) (see Chaudry and Dissanayake 2015). It can be a solo activity, in which objects are treated as if they were something else, e.g., using a banana as if it were a telephone. This kind of play has a crucial role in the theoretical position that autism involves a lack of theory of mind (Leslie 1987). Pretend play can also be social, as in role-playing games such as "playing house" or superhero games. Social play with peers can be a valuable support for developing social skills such as turn-taking, reciprocity, and cooperation (Whitebread et al. 2017). In turn, cooperating with others can be a crucial stepping stone to developing complex group relations and is claimed as an important human evolutionary step (Moll and Tomasello 2007). Again, social play is often different or delayed in autism (Chaudry and Dissanayake 2015).

Given these developmental benefits of play, the design of play spaces for children with autism is clearly important, with potential for providing opportunities for development in exactly those areas that are known to be different or delayed in autism.

Playground Design and Social Interaction

As noted above, children with autism tend to show less or different pretend play, and social forms of play, than typically developing (TD) children. A valuable empirical base demonstrating greater time in solitary and less in social play among

children with autism (30% of time vs. 9% for solitary in ASC vs TD, 40% vs. 70% for more social play) is provided by Locke et al. (2016). The role of design in supporting social play is evidenced in a study by Yuill et al. (2007), who took advantage of the redesign of a school playground to compare play in two settings. Eight 6-year-old autistic boys in the unit were observed for three 45-min lunchtime playground sessions in the old playground, which they shared with children with language difficulties. The ASC group then moved to a new playground designed specifically for them and were observed for three further sessions. The playground was designed to have an appropriate level of physical challenge (e.g., height of slide and climbing walls), support for pretend play (a painted railway track), plans for supporting guided movement (e.g., positioning of the track and the slide exit), and points enabling solitary observation and nonparticipation. Solitary play reduced from about 37% to 21% of the time, and the more social form of group play increased from 10% to 24%. Social initiations also increased significantly. Surprisingly little further naturalistic research of this type has been reported.

Important Considerations in Play Design

Two concepts in the field of design have particular relevance for autism. First, there is a strong movement for participatory design, where the people who might use facilities are involved, from the very earliest stages, in planning and designing the facilities. In autism in particular, many advocate that research and intervention generally need to be much more participatory than in the past (Frauenberger et al. 2017). For example, Frauenberger et al. asked minimally verbal autistic children what objects they wanted to design, rather than designing to an external brief and then providing a set of limited, pre-defined choices of features such as color or shape.

Second, design can be approached by tailoring designs to the specific needs of a particular group (such as dropped curbs for wheelchair users) or a universal design approach that provides designs to make access possible for an otherwise excluded group, but does not provide obstacles for any

other users: automatic doors are an example (<http://universaldesign.ie/what-is-universal-design/the-10-things-to-know-about-ud/10-things-to-know-about-ud.html>).

A good example of design considerations for integrated intergenerational participation is provided at <http://nda.ie/Publications/Others/Research-Promotion-Scheme/Community-Parks-and-Playgrounds-Intergenerational-Participation-through-Universal-Design1.pdf>.

A further question in design is whether the space is designed to cater for particular behaviors or to change those behaviors in some way, either by discouraging behaviors some might perceive as unhelpful (e.g., banning fidget objects that support stimming) or encouraging behaviors seen as desirable (e.g., more social forms of play, opportunities for physical challenge). Christensen and Romero (2016) provide a useful scoping review on design considerations for outdoor play in autism, though this does not include a review of evaluative research.

Integration or Separate Provision?

In relation to play space design in autism, this raises the question of who the space is for. The space might be specially tailored for the perceived needs and preferences of autistic children, or there might be a specific goal to support integration of these children with TD children, perhaps because each group might benefit from interaction with the other. For example, autistic children might observe and learn about typical social behaviors such as cooperation and pretence, while TD children could benefit from understanding better the needs and differences of children with autism. Discussion of integrated vs. separate spaces and information on the design and legislative frameworks in Australia, the UK, and the USA are provided by Burke (2013).

Pragmatically, play leaders will need to decide what will benefit users in particular situations, and thus spaces might be used separately or together at different times. For example, one group might benefit from play equipment being changed frequently, but others, such as many children with autism, might find a predictable pattern more supportive. Play leaders will

also have different aims, and it is useful to be explicit about what these are. Given that play is seen as especially valuable for facilitating social skills and opportunities and that these aspects are part of the definition of differences in autism, much of the research and intervention in playground design has involved design to support social interaction.

Play Interventions

Designs could be made to support interaction between children with autism, or such children with TD peers, or such children with adults. A review of teaching play skills in autism is provided by Jung and Sainato (2013). In the last case, most work has involved structured play interventions, and these will be mentioned only briefly here.

Adult-Supported Play Interventions

Two well-developed interventions of this sort are:

The Integrated Play Group (IPG) model involves adults and “expert” players supporting the play of “novice” players (autistic children are seen as novices here).

Risk, Resilience, Independence, and Agency

There is little work on risky play in relation to autism in particular, and as one might expect, caregivers of children with any difference or disability often have protection from risk as a main concern, rather than opportunity to learn about risk. Serman et al. (2016) provided a systematic review of the few studies in this area highlighting considerations for play spaces for children with disabilities, and Goodley and Runswick-Cole (2010) argue for the need to include risk in spaces for children with

disabilities. Clearly, risk assessments are crucial in any play space design: for a simple approach, see Coleman (2019). Spaces for children with autism need to involve consideration of risks likely in the particular group. For example, a shared space for children with speech and language difficulties and those with autism involved a conflict between frequently changing play objects to provide novelty vs. providing predictability, which some autistic children preferred Yuill et al. (2007). There are also considerations appropriate to children at developmental levels below their chronological age, or with sensory needs, e.g., preventing children ingesting bark chippings or providing a range of objects with interesting sensory properties of touch or smell.

There is little theoretical work in this area in relation to autism, but an increasing amount of practical work and design in relation to TD children and mainstream schools. There is extensive documentation of the philosophy, policy, background, and evaluation of this approach in schools on the Outdoor Play and Learning (OPAL) site: <https://outdoorplayandlearning.org.uk/home/for-schools/research/>.

There is also research into the benefits of teaching children to evaluate risk, particularly in relation to outdoor play, against a background of concerns that perceived fear of litigation for injury will reduce children's opportunities to learn about risk management by making decisions during free play. A small systematic review suggests that benefits of such play include physical health but also social benefits (Brussoni et al. 2015).

Physical Fitness

Menear and Neumeier (2015) provide suggestions based on research about how to support physical activity in play activities for children with autism, with particular focus on the motor difficulties that many such children experience.

Natural Play Spaces

The concept of forest schools and the value of natural objects and environments for well-being generally have been cited as a reason to provide such environments for children with autism.

There is little robust research to evaluate this question, but a useful review of the views and experiences of parents of autistic children in Tongji, China, is provided by Li et al. (2019), suggesting that parents often see the sensory, physical, and social benefits of play may fear its risks.

Virtual Play Spaces

There has been a comparatively large amount of work on technology-supported play spaces (such as virtual spaces) in relation to autism, reflecting the idea that some aspects of physical spaces and the physical presence of others can be overwhelming in autism, with virtual others and spaces providing room to step out of the situation and to have more control over stimulation levels. Several of these are showcased in the Digital Bubbles archive (digitalbubbles.org.uk especially seminar 4]). For example, Pares and colleagues describe an augmented-reality environment, Lands of Fog, that subtly supports users to physically interact with each other in shared exploration of a technology-augmented environment representing a land covered in virtual fog, which can be revealed through peepholes as the players explore it, as well as to play games such as catching "fireflies." New elements and creatures can only be found by acting collaboratively with another player. Over multiple lab sessions, children made more initiations (Mora-Guiard et al. 2017) and different features of the game supported social interaction (Crowell et al. 2019).

Future Directions

As technology and the use of augmented objects and spaces develop apace, there will be further possibilities for the design of augmented play spaces, though it is hard to predict which features and tools will move beyond the experimental demonstration. Concerns about physical fitness and mental well-being through "natural environments" may become increasingly pressing, particularly given environmental degradation and changing global conditions. At the same time, there is substantial room for larger, more

prolonged studies of children's behavior in existing play settings, to test existing ideas about how design influences social behavior. For example, Yuill et al. (2014) report a study of an augmented "knight's castle" playset in which they tracked how the design of the object – which provides play objects with apparent agency to make relevant sounds and speeches as they are placed in different locations – prompted increases in the likely success of a child's attention bid, which in turn seemed to lead to longer bouts of social play. The wider availability of video tracking and automated coding in natural play settings makes this sort of research increasingly possible, and this would deepen our understanding of the mechanics of playground design in shaping and supporting different patterns of behavior in children on the autism spectrum.

Definition

Play therapy is a method of treatment that is provided to children by a trained professional. It uses play within a therapeutic setting to address social, emotional, and behavioral difficulties. Traditionally, the underlying premise of play therapy was that children use symbolic play as a way to represent their internal experiences (e.g., beliefs, feelings) and, simultaneously, can develop and practice healthy coping skills through play. Play therapy is significantly different from the play children engage in with their peers or other untrained adults in their lives (e.g., parents or babysitters) because the therapist interprets children's play behaviors in an effort to achieve treatment goals. There are various forms of play therapy interventions as well as growing empirical evidence for treating childhood difficulties, such as trauma and anxiety. In addition, play therapy has been incorporated into other empirically established treatments for children, such as cognitive behavior therapy. Play therapy varies based on the reason the child enters into treatment, the age of the child, and the training background of the therapist. The therapist observes and joins in the play to obtain a better understanding of the child, connects the information gathered

from these interactions to the reasons for which treatment was initially requested, and then applies this understanding to develop and implement treatment goals. Positive changes are achieved by sharing interpretations with the child in an understandable and child-friendly manner within the play, collaborating with the child to develop and practice better coping skills using play, facilitating communication of feelings and thoughts in a safe and emotionally corrective environment, as well as involving and coordinating treatment goals with the child's family.

At this time, there is no established empirical support for the use of play therapy in treating youth with ASD (National Research Council 2001). Historically, traditional talk and play therapies have not been considered a helpful intervention to address the core symptoms of autism spectrum disorder (ASD), a point noted early in the field by Kanner and others. Impairments in symbolic, imaginary play characteristic of ASD (Stahmer et al. 2003) as well as the strong empirical evidence in support of behavioral interventions based on the principles of applied behavior analysis to treat core ASD impairments (Dawson et al. 2010; Koegel et al. 2010; Lovaas 1987) have precluded play therapy as an intervention for ASD. However, one area of focus of behavioral intervention for children with ASD has been to develop play skills, including symbolic play (Stahmer et al. 2003). Additionally, for children with ASD, play has been used to facilitate functional communication and social skills (e.g., Dawson et al. 2010; Koegel et al. 2010).

Multiple phenotypes associated with disruption of a single gene

Structure

An individual's set of genes is referred to as their *genotype*, and how these genes influence the expression of physical characteristics, or the

presence of a disorder, is considered an individual's *phenotype*. Because most genes encode an RNA molecule or a protein sequence, disruption of a gene by a mutation that prevents it from functioning has the potential to interfere with whatever processes the gene product influences. For this reason, mutations in a single gene or pair of genes may affect organ systems ranging from, for example, the central nervous system, cardiovascular system, and connective tissue. *Pleiotropy* is the genetic phenomenon in which disruption of the same gene results in a range of clinical symptoms. Because multiple organ systems may be affected, often, it is challenging to explain how disruption of one gene leads to such a diversity of phenotypes or clinical presentations (Jorde et al. 2010; Nussbaum et al. 2007).

Although ASDs are considered to be the most genetic of developmental neuropsychiatric disorders, based on studies of monozygotic twins and recurrence risk in siblings, marked heterogeneity at both the genotypic and phenotypic levels has made elucidating the genetic underpinnings of ASD a formidable challenge (O'Roak and State 2008). ASD is characterized by marked *locus* and *allelic heterogeneity*, such that multiple genes at different locations throughout the genome and distinct variants within the same gene, respectively, can influence an individual's clinical presentation. Our current conceptualization of the genetic architecture of ASD is that it is complex, involving the interplay of genetic variation, which may be present in multiple risk genes throughout the genome, inherited or *de novo*, rare or common, and present at the level of the sequence of DNA (single nucleotide variants) or the structure of chromosomes (copy number variants, CNVs); environmental; and epigenetic components – all of which contribute to clinical presentation, which also may be heterogeneous (State and Levitt 2011).

Further complicating our ability to elucidate how genes associated with risk cause clinical symptoms in ASD are emerging findings from recent studies showing that these genes are highly pleiotropic, in that they appear to confer risk for multiple clinical presentations. On the one hand, there is strong evidence for a number of candidate

genes and chromosomal regions, such as *Neurologin 4X (NLGN4X)*, *SH3 and multiple ankyrin repeat domains 3 (SHANK3)*, *contactin-associated protein-like 2 (CNTNAP2)*, 16p11, 22q11, and others (see below), in ASD. However, recent large-scale studies have implicated the same genes and structural variants across a range of psychiatric disorders, including schizophrenia, attention-deficit hyperactivity disorder (ADHD), and Tourette syndrome (TS), and in some cases, neurological disorders, such as seizure disorder, and even obesity (discussed in more detail below). Therefore, pleiotropy has emerged as a central theme in the genetics of ASD, forcing us to reexamine our understanding of how genetic risk informs phenotypic specificity (State 2010; State and Levitt 2011).

Function

There are a growing number of examples of variation in the same gene or chromosome region predisposing to a diversity of phenotypes, including ASD. All of the examples discussed here are genes or CNVs that were initially identified as susceptibility genes/regions through what can be described as a rare variant approach. This approach involves looking for outliers, in particular rare, *de novo* abnormalities in chromosome structure, and is hypothesized to enrich for the identification of genes of major effect. Therefore, there is strong evidence implicating these risk genes and CNVs in ASD, which makes finding these same variants in other disorders difficult to interpret.

One chromosomal region that has been strongly implicated in ASD in multiple studies is 16p11.2. Specifically, structural abnormalities affecting this region have been found in ~1% of families with ASD. These studies showed that recurrent deletions and duplications of this region occur with increased frequency in individuals with ASD. CNVs in this region were found to be either transmitted or *de novo* (Kumar et al. 2008; Marshall et al. 2008; Sanders et al. 2011; Sebat et al. 2007; Weiss et al. 2008). Despite the strong evidence for this region in ASD, CNVs at 16p11 have also been implicated across psychiatric

diagnoses. For example, Weiss and colleagues identified deletions in this region in individuals with schizophrenia, bipolar disorder, ADHD, and dyslexia.

Additional studies provided further support for an association of CNVs, specifically duplications at 16p11 in schizophrenia and childhood-onset schizophrenia (McCarthy et al. 2009; Walsh et al. 2008). Moreover, one of these studies specified that 16p11.2 microduplications were significantly associated not only with the risk of schizophrenia but of bipolar disorder and autism, while the reciprocal microdeletion was associated with autism and developmental disorders (McCarthy et al. 2009). In addition, more recent studies have reported that structural abnormalities in this region are found in intellectual disability that is not associated with autism (Bijlsma et al. 2009) and even in obesity (Bochukova et al. 2010).

Therefore, it would seem that instability of chromosome structure in this region predisposes to a range of psychiatric disorders. However, it is important to observe that CNVs in this region have also been found in unaffected individuals (Glessner et al. 2009). In addition, even some of the first deletions in this region identified in families with multiple affected individuals with ASD by Weiss and colleagues did not segregate with the presence of the disorder, such that affected siblings did not share this CNV. While this observation flies in the face of what would be expected in Mendelian disorders, it is consistent with findings in disorders with complex genetic architecture, such as ASD (O’Roak and State 2008).

Another highly pleiotropic region is chromosome 22q11.2. Deletion of this region causes velocardiofacial syndrome or DiGeorge syndrome, a pleiotropic syndrome that leads to abnormalities in multiple organ systems, including immune deficiencies, cardiac defects, and mild dysmorphic facial features. While CNVs in this region have been associated with ASD (Glessner et al. 2009; Marshall et al. 2008), 22q11 deletions have also been found to increase the risk of a range of psychiatric disorders, most notably early-onset psychotic disorders, schizophrenia, ADHD, and anxiety (Green et al. 2009).

While it seems plausible that pleiotropy might occur due to disruption of a chromosomal region,

which encompasses many genes, it is surprising that single genes and gene families strongly associated with ASD are being implicated in other psychiatric disorders as well. This finding has led to the conclusion that perhaps similar biological mechanisms underlie these seemingly disparate disorders (see discussion below). For example, *neuroligins* and *neurexins*, which are cell adhesion molecules that are found at the synapse and play a role in synapse formation by interacting with each other across the synaptic cleft, and *SHANKs*, which interact intracellularly with neuroligins (Sudhof 2008), and were first identified as susceptibility genes in ASD (Durand et al. 2007; Glessner et al. 2009; Jamain et al. 2003; Laumonnier et al. 2004; Marshall et al. 2008), have also been implicated in schizophrenia (Gauthier et al. 2010, 2011).

Similarly, *CNTNAP2* was identified as a risk gene for ASD because it was disrupted by a single base pair deletion that was found in consanguineous families, such that individuals homozygous for the mutation had a syndrome characterized by focal epilepsy and cortical abnormalities (Strauss et al. 2006). Multiple additional studies, including those adopting both rare and common variant approaches, have provided evidence that disruption of this gene is likely to be associated with an increased risk of ASD. As was the case with the neurexins and neuroligins, subsequent studies have implicated *CNTNAP2* in multiple psychiatric and neurodevelopmental disorders, including intellectual disability, Tourette syndrome, language disorders, ADHD, and schizophrenia (State 2010).

Pathophysiology

How then do we interpret the overlapping clinical presentations associated with the same structural and single gene variants, as described above? Possible explanations that have been proposed in response to these observations include differences in diagnostic assessments, such that social disability could be defined as ASD in one study, and as representative of the negative symptoms of schizophrenia in another (State and Levitt 2011). However, as discussed in State and Levitt (2011),

this scenario is unlikely to account for the breadth of findings described above, particularly given that ASD and schizophrenia, as defined in *DSM-IV-TR*, have distinct diagnostic criteria, ages of onset, and clinical courses. Alternatively, it is possible that variation in the same chromosomal region or at the same locus might produce either gain- or loss-of-function effects, with respect to the gene product that is disrupted, or divergent effects on gene expression, ultimately leading to different clinical presentations. Another possibility is type I error associated with publication bias (State & Levitt).

At the same time, one current model proposes that the high degree of pleiotropy associated with these genes and chromosomal regions predisposes to a diverse range of clinical presentations. More specifically, structural variation at regions such as 16p11 or 22q11, or sequence variation in risk genes, including *NLGN4X* or *CNTNAP2*, may represent a risk for the disruption of common biological processes, such as synapse formation. Variation at other sites throughout the genome, i.e., locus heterogeneity, interacts with the known risk variant(s) to influence the same biological processes. Moreover, environmental and epigenetic factors also affect gene expression and these same processes in ways that are not well understood (State 2010; State and Levitt 2011).

Support for this hypothesis comes from recent whole-exome sequencing studies of families with developmental brain malformations, in which homozygous mutations in the gene *WDR62* were found to lead to multiple distinct cortical abnormalities, including microcephaly, lissencephaly, and hypoplasia of the corpus callosum (Bilguvar et al. 2010). Because psychiatric disorders involve behavioral abnormalities, which are markedly heterogeneous, it is possible that disruption of a single gene is even more likely to predispose to a range of behavioral symptoms. Taken together, according to this model, neurodevelopmental processes are uniquely shaped by the combination of variation in pleiotropic genes/regions, their interaction with other genetic loci, and environmental factors, which has the potential to result in a diverse range of neuropsychiatric disorders (State 2010; State and Levitt 2011).

Definition

Pneumoencephalography is a medical procedure allowing for the structure of the brain to show up more clearly on an x-ray. First introduced in 1919, this procedure uses a lumbar puncture to remove cerebrospinal fluid from the brain, and then air, helium, or oxygen is injected into the lumbar subarachnoid space. See Brown (2012) for description of the procedure and example image. The procedure is rarely used due to significant side effects. It has been replaced by CT scan and other imaging techniques (Kirkman 2015).

In 1968, Aarkrog reported 25 of 46 children with infantile autism or borderline autism had an abnormal PEG (Aarkrog 1968; also see Melchior et al. 1965). Hauser et al. (1975) reported on 18 cases with autism and PEG and found enlargement of the left ventricular system (13/18) and widened left temporal horn reflected in flattening of the hippocampal contours (15/18); only one case was reported as “normal.” The authors concluded that deficits of the medial temporal lobe may be a contributing factor to infantile autism.

Point-Light Displays

Martha D. Kaiser

Child Neuroscience Laboratory, Yale Child Study Center, New Haven, CT, USA

Definition

Point-light displays are constructed by recording movements of people, animals, or objects with markers or point lights attached to the major joints and then processing the videos so that only the point-lights are visible in the resultant displays. These stimuli are used to isolate motion perception processes as they contain limited form information.

Individuals with autism are able to identify human actions in point-light displays. Some behavioral studies indicate typical performance by individuals with ASD on a variety of tasks with point-light displays. However, disruptions in their visual sensitivity to point-light displays of human motion have been found in a variety of tasks including preferential attention, direction detection, and coherence detection. Some studies have reported deficits in labeling emotion in point-light displays. Unlike typically developing individuals, those with autism do not show an enhanced ability to detect human versus animal motion in point-light displays.

Functional magnetic resonance imaging studies present more consistent results as individuals with ASD have repeatedly been found to exhibit

atypical neural responses to biological motion in point-light displays. The posterior superior temporal sulcus is one area of dysfunction reported in such studies. Some researchers have proposed that PSTS dysfunction and disrupted perception of biological motion (in point-light displays) serve as a hallmark of autism spectrum disorders.

Police-Citizen Interactions, Theory of Mind, and ASD

Neil Brewer and Robyn L. Young

Flinders University, Adelaide, SA, Australia

Definition

This entry focuses on how theory of mind (ToM) deficits may (a) lead to ASD individuals becoming involved in problematic interactions with the police and (b) shape their ability to negotiate such interactions effectively.

Historical Background

Discussions of problematic social interactions that are often experienced by ASD individuals frequently refer to a deficit in theory of mind (ToM) – or what in everyday parlance might be labeled perspective taking – as a key underlying factor. Indeed, some have argued that a ToM deficit is a core deficit which can explain many of the behaviors that characterize ASD individuals (e.g., Baron-Cohen 1995), although this perspective is not universally accepted (e.g., Van de Cruys et al. 2014). ToM refers to the ability to understand the mental states of others, that is, the ability to take the perspective of others and interpret their intentions, their desires, and even their emotions. Individuals with well-developed ToM should be able to infer the underlying or real meaning of the nonverbal and verbal behavior of those with whom they are interacting. Thus, they should be able to read the meaning behind another individual's facial expressions and bodily gestures. They should be able to read the real meaning behind the vocal tone and verbal expressions of others, thereby enabling them to infer if someone is being sarcastic or is trying to trick them, if someone is using figurative speech (e.g., a metaphor) and thus what they say should not be taken literally, or if the other person's reaction to something they have said indicates they have made a faux pas. In other words, well-developed ToM allows the individual to behave in what might generally be considered to be a socially appropriate and adaptive manner in interactive contexts. An impaired ToM provides a convenient explanation for a variety of social inadequacies and misdemeanors.

Perhaps not surprisingly, therefore, ToM deficits have been implicated in hypothesizing about why some ASD individuals become (a) involved in criminal activity and (b) why their ensuing interactions with the police and the courts may become problematic. We use the term “hypothesizing” because much of the available “evidence” comes from case examples. For example, Brewer and Young (2015) described numerous cases where ASD adults apparently became involved, almost unwittingly, in some criminal activity

because, in a desire to accommodate, please, or impress some third party, they did not recognize that party's criminal intentions or failed to appreciate the wrongfulness of their behavior and the impact their behavior had on the victim(s). Further, when interacting with the criminal judicial system, irrespective of any wrongdoing, they behaved in a way that was not helpful. In each of the cases presented, ASD individuals either failed to understand or react to the caution that they were not required to say anything when questioned and that what they said may be used in evidence. Consequently, they continued to engage with the police, often leading to a negative outcome.

How might ToM deficits have contributed to problems such as those just outlined? ASD individuals with deficits in ToM may have (i) behaved inappropriately toward another person because they failed to recognize the cues from that person that indicated their behavior was problematic, (ii) raised the ire of police officers because, having failed to accurately interpret their expectations, they reacted with inappropriate antipathy toward them, (iii) responded inappropriately to reasonable requests from police or court officials because they interpreted figurative language literally rather than in the manner it was intended, or (iv) failed to appreciate that behaviors (e.g., gaze aversion, fidgeting and shuffling, inappropriate emotional reactions) they manifested during investigative or courtroom interviews may have been interpreted as signs of untrustworthiness, indicative of attempts to deceive, or signs of non-cooperation.

ToM deficits may contribute in other ways that prejudice the outcomes of ASD individuals' interactions with police. In all the cases described by Brewer and Young (2015), the interactions with police led to the production of evidence that was used against them. In none of the cases did any of the individuals exercise their right to silence. Given poor ToM, an ASD individual may fail to appreciate that the mindset of the police officers contrasts to their own mindset. For example, Kassin and Norwick (2004) argued that when people believe they have nothing to hide, they also believe their innocence will

save them, referred to as the “innocents’ mindset.” This “illusion of transparency” leads people to infer that their “inner thoughts or emotions are readily apparent to others.” A well-developed ToM may, however, enable one to detect that the other person’s mindset differs from theirs, rendering the individual less vulnerable to engaging in interactions that do not help their case.

Our focus here, however, is not to rehash the array of case study evidence that is consistent with the perspective that ToM deficits may contribute to problematic interactions between ASD adults and the police and ultimately to adverse interactions in the courts. Rather, we present empirical evidence – limited as it is – that highlights the importance of ToM deficits and provide some direction for future research that should broaden our understanding of the nexus between ToM deficits and problematic interactions between ASD individuals and criminal justice system professionals.

Current Knowledge

From the outset it is important to emphasize that we are not suggesting some well-established connection between ASD and crime commission. A number of studies have attempted to examine that issue using a variety of approaches, including investigating whether autistic individuals are overrepresented in prisons and forensic psychiatric facilities, among specific categories of offenders or individuals with recorded interactions with the justice system, or in crime statistics within community samples. Making sense of that body of research literature is not easy due to question marks about issues such as the reliability of the ASD diagnostic information, the possible contributions of comorbid psychiatric disorders, the adequacy of study sample sizes, and biases within the justice system with respect to the differential disposition of cases involving ASD versus typically developing individuals. Nevertheless, following a comprehensive review of the various types of “crime prevalence” studies, Brewer and Young (2015) concluded that the most justifiable conclusion based on present knowledge

is that the prevalence of ASD individuals’ involvement in crime is probably not too dissimilar to that of the broader population.

Nevertheless, as we indicated in the previous section, some researchers have suggested – based largely on case study analysis – that deficits in ToM or perspective taking typically associated with ASD could, under adverse circumstances, heighten the risk of involvement in crime and contribute to negative interactions with police officers and (ultimately) within the court system. Here we examine (what we believe to be) the only published studies to date that have investigated an empirical relationship between ToM abilities and the possibility that ASD individuals may find themselves falling foul of the law. Notably, all of these studies have only been published very recently. Two of the studies focus on the relationship between ToM and the ability to detect suspicious behavior or attempts to deceive in others. In other words, they explore the possibility that ToM deficits could – by preventing an ASD individual from recognizing the true intentions of the individuals with whom they are interacting – contribute to their becoming involved almost unwittingly in criminal activity. The third study demonstrates how ToM predicts whether ASD individuals suspected of involvement in some criminal activity are able to allay the suspicions of police officers and extricate themselves from a problematic legal situation.

In the first study, Brewer et al. (2018) examined whether ToM predicted how quickly individuals detected there was something suspicious about the way an interaction was unfolding. The researchers examined whether individuals who are poor at taking the perspective of others were slow to recognize that they were being lured into a problematic interaction that may lead them to become enmeshed in some criminal activity. Using a laboratory research paradigm, typically developing participants listened to a number of audio vignettes and were asked to press a button as soon as they detected that something suspicious was going on (or decided that there was nothing untoward about the interaction). Some vignettes gradually unveiled subtle indicators of suspicious behavior by one of the characters, with

the sequence of events culminating in another character becoming unwittingly involved in a crime. Other vignettes had similar story lines but did not culminate in a crime. ToM was assessed with the Frith-Happé animations task (White et al. 2011) in which participants completed a number of trials on which they had to decide whether the “interactions” between a pair of animated geometric stimuli (i.e., triangles) were (i) random, (ii) purely physical, or (iii) mental (i.e., social in nature) with one triangle responding to the other triangle’s mental state. And, if participants deemed the interaction to be mental or social in nature (i.e., requiring ToM), they were asked to attribute feelings to the interacting stimuli.

The findings (and meta-analysis) of two experiments confirmed that, even after controlling for verbal IQ, participants who performed more poorly on the ToM measure were slower to respond to the subtle cues to suspicious behavior. Specifically, the slower detectors of suspicious behavior were less effective at (a) discriminating mental state (cf. non-mental state) interactions between the animated triangles, (b) identifying the specific nature of those mental state interactions, and (c) categorizing the feelings of the animations during the mental state interactions.

Some important caveats were highlighted by the authors. The study was correlational in nature, the relationships (while statistically significant) were not strong, and the sample comprised only typically developing participants (likely limiting the variance in ToM). And, of course, there is no guarantee that the observed slower detection of suspicious behavior associated with poorer ToM would be duplicated in real-life contexts or translated into involvement in criminal acts. Nevertheless, the findings are promising, especially as the strength of the relationships identified was likely constrained by (a) latency measures that inevitably will be “noisy” when based (as they were) on a very small number of trials and (b) limited variance on the ToM measures within a purely typically developing sample. Moreover, the research provides one example of an experimental paradigm that could be refined and used to explore questions that hitherto have evaded systematic empirical investigation.

In the second study, Williams et al. (2018) examined the relationship between ToM (or mindreading as they labeled it) and the ability to detect deception. Clearly an inability to detect attempts to deceive by an interaction partner could render an individual vulnerable to becoming involved in some criminal activity and incurring the wrath of the law. The deception detection paradigm involved participants viewing video clips of interviews with university students who either lied or told the truth about cheating in an experiment; the ToM measures were the triangles’ animations described above and the Reading the mind in the eyes task (Baron-Cohen et al. 2001a).

In their first experiment with typically developing participants, Williams et al. (2018) found no relationship between lie detection performance and ToM measures, but they did detect a significant negative relationship between lie detection performance and scores on the Autism-Spectrum Quotient (AQ; Baron-Cohen et al. 2001b), a measure of autistic traits. In their second experiment, they compared deception detection performance of an ASD sample with that of neurotypical controls. There were two main findings. First, in the combined sample, AQ performance was again negatively correlated with deception detection performance. Second, the ASD group performed significantly worse than controls on the deception detection task. Unfortunately, however, ToM (or mind-reading) was not measured in the second experiment, and thus the possibility that it may have played some mediating role in the sizable group differences reported cannot be assessed. The absence of a relationship between lie detection performance and ToM measures in their first experiment led Williams et al. to conclude that lie detection ability is not related to ToM. However, in line with the comments we made previously in relation to the Brewer et al. (2018) studies, this conclusion seems premature given the likely restricted variance on the ToM tasks when only neurotypical participants are assessed. Given the meaningful relationships detected between the degree of autistic characteristics and deception detection performance, and the sizable ASD-control group differences in deception detection, further exploration of the possible

nexus between ToM deficits and deception detection, particularly within an ASD cohort, certainly seems warranted if we are to appreciate fully the potential vulnerabilities of ASD individuals.

The third empirical study examined concerned another type of situation. Individuals who become involved in criminal activity – whether that involvement is unwitting or not – are obviously at heightened risk of finding themselves in very difficult interactions with the police. But, of course, some individuals may become innocent suspects in a criminal matter through circumstances beyond their control. For such individuals the nature of their interactions with police may determine whether they remain under suspicion, are charged with committing a crime, or are no longer suspected of involvement in the crime. Young and Brewer (2019) hypothesized that ToM (or perspective taking) deficits might affect whether ASD individuals are able to allay (misguided) suspicions that police officers may have about their involvement in a crime – before the police become absolutely convinced of their guilt. They argued that a person who is (mistakenly) suspected of being involved in some criminal activity needs to present information to the investigating officer that will demonstrate their innocence (e.g., providing an alibi that places themselves elsewhere at the time of the crime or suggesting witnesses who might corroborate their account of events).

Young and Brewer identified an array of factors that might contribute to how effectively a person could allay a police officer's suspicions and extricate themselves from a problematic situation (e.g., deductive reasoning capacity, sociability, effective relational processing that permitted coordinated episodic memory recall). One other potentially important factor is their ability to put themselves in the shoes of the police officer and appreciate their perspective on what had transpired. Then, guided by any insights gained from considering the officer's perspective, they would identify and present to the police any information that would demonstrate their innocence, thereby extricating themselves from a very difficult situation. Following this rationale, Young and Brewer (2019) examined two main questions. First,

did ASD adults perform more poorly than IQ-matched controls in providing critical information that would allay misplaced suspicions about their involvement in some crime? And, second, did perspective taking deficiencies play a role in any group differences observed in the individuals' ability to extricate themselves from a difficult situation?

The key perspective taking (i.e., theory of mind) measure was provided by the social items of the adult-theory of mind test (A-ToM; Brewer et al. 2017) in which participants view six videos of interpersonal interactions between actors and are asked to explain the social inferences (e.g., sarcasm, bluff, faux pas) underpinning the behavior of one actor toward the other. The extrication measure comprised five audio scenarios, with participants asked to assume the role of a person in the scenario who is suspected of committing a crime (refer Young and Brewer 2019). Participants listened to each scenario and were then asked to offer as much relevant information as they could in order to convince police they were not involved in the crime. There were four items of information in each scenario that, collectively, would clearly demonstrate the individual's innocence, with participants awarded one point for each item correctly reported.

Young and Brewer's (2019) findings were as predicted and the effect sizes robust. The ASD participants performed significantly worse than the controls on both the ToM and the extrication measures. And, after partialling out verbal IQ and performance on a standardized test of episodic memory, ToM task performance made a substantial contribution to the prediction of extrication task performance. These results parallel case study observations (e.g., Brewer and Young 2015) that ASD adults, wrongly suspected by police of criminal behavior, may not be particularly effective at allaying police suspicions and removing themselves from the focus of any ongoing investigations.

The evidential base provided by these three studies is clearly limited. Although it is not unusual to read that some characteristics of ASD individuals may render them vulnerable to being ensnared in criminal activity and experiencing

problematic interactions with police officers, empirical investigations of these issues are scarce. This almost certainly reflects, at least in part, an absence of well-developed research paradigms for exploring such issues. We have discussed the few studies of which we are aware that represent initial explorations of these issues. The results suggest that the ToM or perspective taking deficits that are more likely to characterize ASD than typically developing individuals may impede their ability to recognize suspicious behavior, to detect deception, and to make a case to police that they should not be a suspect for a crime in which they weren't involved. Clearly, these findings are preliminary. The results have not yet been replicated. In the first two studies examined, the effects were not strong. And methodologies that involve participants reacting to audio or video recordings are some distance from the real-life contexts the studies are seeking to simulate. That said, the findings to date highlight the likely connections between ToM deficits and the ability of ASD adults to respond adaptively in a complex social environment. Moreover, from an applied perspective, empirical demonstrations of how problematic interactions with the criminal justice system could surface for ASD individuals are crucial for illuminating potential biases in the operation of the justice system and developing an informed framework for the education of police and court officers.

Future Directions

Despite the abundance of comments in the literature about the characteristics of ASD that could, in some situations, render individuals vulnerable to becoming involved in crime and experiencing quite negative interactions with police and the courts, it is clear from the preceding analysis that empirical work in this domain has barely got off the ground. This of course means that the opportunities for future research are boundless. Consequently, in this section, we have chosen to highlight a few issues – not in any particular order – that we think are of high priority.

One important focus of future research should be on enhancing our understanding of ToM in

adult ASD individuals. Although implicating deficits in ToM may provide a parsimonious account of unusual or problematic social behavior, there is only limited empirical evidence regarding the nature and extent of those deficits and how they are reflected in ASD adults' behavior. There is some evidence of significant variability in ToM deficits across adults (Brewer et al. 2017), with some individuals differing little from typically developing controls and others being markedly impaired. But it is important to recognize that the breadth of behaviors sampled by ToM measures, such as the A-ToM used by Brewer et al. (2017), is quite limited, so little is known about whether the deficits are pervasive or, perhaps depending on the individual's social learning experience, manifested only in quite specific behavioral domains (cf. Brewer and Young 2015). Further, although poor ToM may account for social and communication difficulties, its link to stereotypical and ritualistic behaviors, sensory responses, and other core features of the disorder is unknown. Therefore, the inter-relationships between all these features of ASD that may lead to ASD individuals becoming involved in problematic interactions with the police, and shape their ability to negotiate such interactions effectively, remain unexplored.

Another focus should be to replicate and extend the preliminary findings we have described above. Extending this initial research will obviously require the development of novel research paradigms that ideally will more closely parallel the demands of real-life interactions. It would also be desirable for such research to capture other dimensions of police-citizen interactions in order to appreciate the extent to which ToM deficits constrain the ability of ASD individuals to interact effectively. For example, tendencies to acquiesce to other people's requests and to interpret statements in a completely literal manner are often mentioned as characteristics that could seriously disadvantage ASD individuals when interacting with the police or lawyers (e.g., Beardon et al. 2018). Likewise, being insensitive to facial expressions or vocal tone and volume of a police officer with whom they are interacting may contribute to a rapid deterioration in their

relationship. Yet, empirical work that helps to clarify the individual perspective taking characteristics and the potentially enabling situational variables required for such problems to emerge has not yet been conducted.

Similarly, there are numerous behaviors often seen in ASD individuals (e.g., gaze aversion, fidgeting, inappropriate affect, monologues) that if manifested in an interaction with a police officer (or in the courtroom) may lead to the individual being judged quite harshly (for a detailed discussion, see Brewer and Young 2018). However, empirical work that captures whether ASD individuals are sensitive to these judgments of their behavior, and then able to adjust their behavior accordingly – or are even motivated to do so – is non-existent.

Finally, we draw attention to an area previously highlighted by Brewer and Young (2018). It is well documented that the Internet offers opportunities for individuals to be deceived and exploited. Whether ASD individuals are particularly vulnerable when interacting in this environment is unknown. But survey data do indicate that many ASD individuals keenly maintain interests that are often pursued using the Internet, potentially exposing individuals with limited social networks and ToM deficits to interactions in chat rooms or other networking frameworks with individuals who may have nefarious intentions. And those with perspective taking deficits may be slow to see where such interactions are heading and unskilled at extricating themselves from any problematic situations before they end up violating the law. Systematic empirical research in this domain using imaginative new research methodologies certainly appears to be a potentially worthwhile direction.

The research directions we have outlined are obviously just a select few. The relevance of many or all of them has doubtless been raised in policy documents, canvassed in the informal observations of clinicians, and so on. However, we believe that persuading police, lawyers, and other justice system professionals of some of the barriers to ASD individuals receiving equitable treatment in the justice system will be enhanced significantly if, rather than relying on clinical

anecdotes, there exists a body of systematic and demonstrably reliable scientific evidence that clearly pinpoints the nexus between prevalent ASD characteristics and the likelihood of problematic justice system interactions. In sum, this seriously neglected research area offers enormous challenges to interested and skilled researchers, challenges that, if resolved, can help ASD individuals and increase the chances that they receive equitable treatment when interacting with justice system professionals.

Politics of Autism

Lynn Adams
New Orleans, LA, USA

Synonyms

Autism policy; Public understanding of autism

Definition

Autism viewed as an issue about which an individual can have an opinion and for which the government can program. The politics of autism began with the term's first use by Eugen Bleuler in 1910, developed as knowledge about autism grew, and continue to change.

Scientific research informs autism policy, but so do less trustworthy sources such as personal accounts, lived experience, and media coverage. Theories compete for finite funding and interest, creating conflict between groups that have the same goal: to improve the lives of people affected

by autism. Each new controversy regarding autism increases its visibility. Unfortunately, controversies also breed conflict, which fragments understanding and policy.

Multiple key aspects of autism have been in dispute all along: prevalence, theories of causation, interventions, and outcomes.

As prevalence numbers have increased, so has the perceived importance of autism. What began as a rare condition has since been referred to as an epidemic, as the theory that autism cases were on the rise peaked in the 1990s. Leo Kanner's 1943 definition of autism was updated with the publication of the DSM in 1952, followed by multiple revisions progressing to the most recent DSM-5. Diagnostic changes have played a part in fluctuating prevalence figures and have also complicated professional and public understanding. Without agreement on what autism is, we can't say for certain how common it is.

Early causal theories such as the refrigerator mother theory in the 1960s contributed to a stigma associated with autism that persisted for decades. The parental experience of autism influenced its politics, as parents began by being blamed, then became central to intervention and advocacy. All along, parents faced public perceptions of their children's condition and the stress of living with it. As each generation of autistic children matured, they had more opportunities to advocate for themselves. The development of the Internet accelerated the spread of information, misinformation, and support (Pitney 2015).

Causal theories and related treatments that were later debunked attracted funding and public attention. In the case of the late 1990s vaccine theory of autism, the process of debunking the theory also drained funding for a prolonged time period (Offit 2008). More recently evidence of genetic causes drew research funding but drew it away from those who were already living with autism.

As certain interventions emerged as more effective than others, funding and interest followed. Here was another central controversy. Does autism intervention aim to cure autism or to help those with autism accommodate themselves to a mostly non-autistic world? And what fields would provide interventions? Medicine? Early

Intervention? Education? Social Services? Did we set people with autism apart to treat them, or did we include them in mainstream settings? In the 1990s, applied behavior analysis drove demand for costly early intervention programs, shifting the focus away from the lifetime approach advanced by state-funded programs such as Division TEACCH (Mesibov et al. 2004).

Finally, desired outcomes are still in question. One person's perceived success could resemble another's perceived failure. For some, the ability to live independently is enough. But what about those for whom such an outcome is out of reach, no matter how much intervention they receive? Conversely, have those who completed college, found meaningful work, and raised families been cured? The focus on a cure peaked as applied behavior analysis offered a 50 % cure rate at the height of its popularity (Lovaas 1987). At the same time, though, adults with autism emphasized the positive aspects of their differences and questioned the need for a cure. More recent thinking has turned to the most likely positive outcomes and how to use resources to achieve these (Siegel 2018).

Just as a focus on prevention, treatment, or palliative care varies in popularity during a person's lifespan, autism has meant different things to different people over the generations since the term was first used.

Politics of Autism Transition Services

Eric Benninghoff

Yale University, New Haven, CT, USA

Definition

A political analysis of why the transition and adult service systems are such problematic parts of autism policy, how transition has been addressed by stakeholders with differential success, and what the implications are for politics and policy moving forward.

Historical Background

Autism Transition as an Escalating Policy Crisis

Not long ago, autism was a condition unknown to the American public. Those who had it were typically kept at home or thrown into large institutions with other special needs groups society had given up on. Now, autism is known to be the fastest-growing serious developmental disability in the United States (Ardhanareeswaran and Volkmar 2015) – affecting an estimated 1 in 54 Americans (Centers for Disease Control 2020). With increasingly high rates of diagnosis and the boundaries of the autism world continuing to push out, the condition has officially emerged as a major issue in American public policy.

Although much of the attention of researchers has been on autistic children, many of the biggest policy challenges revolve around the transition services system – meant to support young adults with autism in their transition to adulthood.

For any young adult, transitioning into adulthood – by attending college or finding a job – comes with challenges and a period of adjustment. But for people with the social, emotional, and communication challenges that often coincide with autism, this period of transition becomes significantly more difficult to traverse, especially given the continued growth in white-collar and service sector jobs that require exactly the interpersonal skills autistic people often struggle with (Pitney 2015). With over half a million Americans on the spectrum legally entering adulthood and aging out of school-based services over the next decade (Harwood and Novotny 2017), this problem will only gain in significance.

More than half of autistic young adults remain unemployed or unenrolled in higher education for their first 2 years out of high school, which is the highest rate among disability groups (Autism Speaks 2020). This is despite the fact that employment is the primary transition goal of students with special needs exiting high school (Roux et al. 2015). Mass unemployment is taking a toll on autistic adults, who are losing out on the benefits associated with job activities, including greater independence, the reduction of autism symptoms, and increased daily living skills (Autism Speaks 2020). According to Autism Speaks, the national cost of supporting people with autism reached \$268 billion in 2015 and is expected to rise to \$461 billion by 2025 without more effective support across the lifespan (Autism Speaks 2020).

The diversity of the autism experience makes transition particularly challenging to tackle from a policy perspective. What works for one person in terms of transition likely won't work for many others, which makes individualization of programming and services important. This often requires significant investment in staff and training, which comes at a high cost.

A common feature of the transition experience for autistic individuals and their families is confronting the challenge of the services cliff. "Falling off the cliff" refers to the shift from receiving school district entitlement services to traversing a dizzying bureaucracy of non-entitlement programs once an autistic individual

turns age 22. Its presence largely exists because the United States lacks a well-organized infrastructure to implement necessary services once people with autism leave the education system. "After the cliff, finding services is a maze with high walls and a hidden entrance. You don't know where to start" (Pitney 2020).

Multi-year waitlists for transition and adult programs are not uncommon in many states after age 21, largely due to limits in state and federal funding. Families are often lost trying to navigate a complex system of state agencies and other service providers that help with job placement, vocational training, and other employment-related programming. A significant burden is placed on parents, as fear mounts regarding who will take care of their child once they die. Alleviating the harsh impact of the services cliff is crucial to facilitating greater independence among the autistic population in a way that elevates quality of life and lessens the financial strain on state and federal budgets (Loomis 2014).

Political Science: A Newly Studied Window into Understanding Transition

The way in which the transition issue is addressed by government provides a window into the politics of social and education policy for historically stigmatized groups, as well as the way policymaking plays out in a decentralized federal system. Moreover, politics provides a lens with which to better understand the tensions that challenge the transition services system, helping to answer the core question of why it is such a problematic part of autism policy.

Only a handful of political scientists have closely studied autism as a policy issue. This entry builds on Professor John Pitney's scholarship articulated in his book *The Politics of Autism: Navigating the Contested Spectrum*, which serves as a primary framework for understanding how politics operates in this space.

Federalism – or the distribution of political power across federal, state, and local government units – shapes the environment in which autism transition politics play out. It provides multiple venues at which to obtain services but also adds to the complexity of navigating sometimes-dizzying

bureaucracies to find them (Pitney 2015). Because autism transition services are intertwined within this decentralized federalist political structure, there's not one central place where policy and services are created and implemented. Instead, "various providers offer various services, with various levels of support from the government, which largely depends on where one lives" (Pitney 2015, p. 5). This makes coordination among entities within the autism transition system an ongoing challenge.

Utilizing federalism as a lens helps illustrate how the transition system is constructed and, moreover, portrays the tensions, money clashes, implementation battles, and mobilization efforts that continue to shape and challenge its structure, across states and localities nationwide.

A Brief Political History of Autism as a Policy Issue

The historical background of how autism became an increasingly visible political issue throughout the twentieth century helps portray the larger forces – including misunderstanding, prejudice, "legislative oversight," (defined here as the unintentional failure to accommodate a group when creating policy) and policy fragmentation – that have shaped the current transition services system.

Nowadays, autism is understood as a national issue affecting millions of Americans, impacted by the actions of the government, school system, and numerous welfare policies. The boundaries of the autism world continue to push outward as more people receive an autism label and see themselves as part of the issue (Pitney 2015). But this was not always the case. For an issue to enter the public agenda, it must first be seen as a problem, which often relies on a shift in awareness and understanding (Pitney 2015). In the case of autism, this did not happen until the late twentieth century. "Its emergence hinged on its identification as a distinct disorder, on public knowledge of its existence, and on changing beliefs of what causes it and what to do about it" (Pitney 2015, p. 16).

Misunderstanding and misinformation characterized what many early researchers and clinicians

said about autism, often describing it as an affliction of the young caused by "refrigerator parents," who lacked warmth in raising their children. Casting blame on parents suggested there was little the government could do to help, which not only kept autism off the political agenda but also "immobilized the child's strongest ally" (Rimland 1970, p. 20). Additionally, the historic inability to recognize autism as a lifelong condition had reverberating effects on why today's service system is built more for autistic children than adults.

As scientific misunderstandings slowly began to clear, and diagnostic criteria became more refined, various political forces were at work paving the way for autism's emergence on the agenda. The Civil Rights Movement of the 1950s and 1960s helped make way for the Disability Rights Movement that would follow, which started gaining traction after the election of John F. Kennedy – whose sister lived in an institution for people with intellectual disabilities (Pitney 2015). The years that followed were characterized by the passage of key pieces of civil rights legislation that banned discrimination or exclusion based on disability, including the 1973 Rehabilitation Act, 1975 Education for All Handicapped Children Act, and 1990 Americans with Disabilities Act.

These pieces of legislation helped frame autism as a rights-based issue, making lawsuits and implementation battles common, particularly between parents and school districts in relation to special education. It is crucial to note that many of these foundational laws, still shaping the government's response to autism and other conditions today, were ambiguous and typically not written with autistic people in mind – because they were created before autism had a more prominent place on the political agenda (Pitney 2015). These weren't deliberate decisions, but they created a need to infer the standards conveyed by the laws without specific reference to autism. The challenge is that services required for people with autism are typically far more complex and sophisticated than these laws recognized (Pitney 2020). This historic "legislative oversight" helps explain why such a massive burden is placed on parents when seeking services for autistic children,

whether related to transition or other facets of life (Pitney 2020).

The tide began to change in the 1990s, “when legislative, scientific, and social trends converged to make autism an increasingly prominent political issue” (Pitney 2015, p. 26). Congress reauthorized the Education for All Handicapped Children Act, and this time autism was listed as a distinct category for special education. This new law, renamed the Individuals with Disabilities Education Act (IDEA), would have major consequences on educating people with autism, including within the transition space.

Now that the autistic population was clearly included under IDEA and formally entitled to a free, appropriate public education and related services from ages 3–21, schools had to begin identifying people with autism who qualified for services. As a result, the diagnostic criteria became much broader, and the number of people receiving services for autism spiked rapidly. From 1995 to 2018, the number of autistic children aged 3–21 receiving IDEA services increased from 28,000 to 710,000, with ASD now accounting for about 10% of the total population served under the law (National Center for Education Statistics 2009, 2019). This drastic growth in identification and observed prevalence drove public awareness of autism and enabled more families to push for services for their children (Pitney 2015). But it also increased financial pressure on school districts and, later, transition service providers, who now had to provide more programs for people with ASD.

For most of American history, states and localities dominated education policy. Starting in the 1950s, however, the federal government began to assume a bigger role. The Education for All Handicapped Children Act and IDEA – which increased federal funding for special education and required greater inclusion of people with disabilities in K-12 schooling – were a product of this growing federal involvement (Pitney 2015). But when Congress passed these landmark bills, national leaders failed to anticipate how much educating a child with special needs would cost. Nor did they foresee how many young Americans would qualify for such support. Under the 1975

Education for All Handicapped Children Act, the federal government was authorized to cover “40% of each state’s ‘excess cost’ of educating children with disabilities” (Pitney 2015, p. 65). Yet the federal government has consistently fallen far short of this federal financing standard. As a result, states and school districts have struggled to meet federal standards. This imbalance between federal requirements and federal support has contributed to the challenges many autistic young adults face when trying to obtain sufficient transition support.

Current Knowledge

Federalism and the Politics of Autism Transition

The historical background of autism as a policy issue begins to illustrate the configuration of political forces continuing to challenge and shape the transition system today. Ultimately, political and policy fragmentation, “legislative oversight,” and a culture of low expectations for autistic adults combine to create an unstable and unnecessarily complex transition services infrastructure riddled with implementation battles, clashes of money and values, and confusion. As a result, people with autism face a service system – often consisting of poorly matched parts originally designed for other populations – that is extremely complex to navigate, places undue burden on students and parents, and varies vastly throughout the country.

Tensions and clashes are common in autism transition politics because there are many stakeholders motivated by different priorities and limited by different resources and pressures. Autistic people are the ultimate stakeholder, trying to obtain the services and opportunities necessary to support their unique abilities and help them live a fulfilling life. Autistic voices have often been absent from public conversations on this topic, largely due to prejudice and stigma.

Parents are another key stakeholder in autism transition. An immense burden is placed on them to enforce their children’s rights and find the services and support needed. Parents often know

the unique needs and abilities of their children best and try to demand more than simply the “free and appropriate education” IDEA guarantees. Some parents are more equipped to take on this advocacy role given factors such as wealth and education.

As the primary provider of services through age 21, school districts are another key stakeholder in the system – organizing the creation and implementation of the individualized education and transition plans (IEP and ITP). The major challenge is that autism can be an expensive label at a time when states and local districts are almost universally under budget pressure (Pitney 2015). Thus, when attempting to provide the transition services necessary to best prepare students for adulthood, school districts are often at odds between their federal obligation and surviving financially.

Particularly once school district IDEA entitlements expire, out-of-school service providers offer employment support including vocational training, job coaching, and day habilitation programs. There is no specific government agency designed to exclusively meet the needs of young adults with autism transitioning into employment (Gerhardt et al. 2014). As a result, adolescents transitioning into the vocational world have to choose from a variety of private and public programs designed for people with many different developmental disabilities.

Ultimately, the state and federal governments are the macro-level stakeholders within the larger system. State legislatures appropriate budgets and funding to state agencies and school districts, which are used for programs that support autistic young adults. Meanwhile, federal funding has a significant impact on state reimbursements for special education, services such as Medicaid, and federal autism research. In addition, state and federal governments set up the policy structures under which the rest of the system operates, as illustrated by IDEA’s influence on special education nationwide.

When these stakeholders, with varying priorities, pressures, and resource limitations, come into contact with one another in the transition services system, tensions, implementation battles, and

clashes of money and values play out. A primary example of this occurs between families and schools, particularly during meetings involving the creation, and yearly review, of IEPs and ITPs.

“IEP meetings often represent a clash of conflicting outlooks” between parents who want the best outcome for their child and school districts that are often dutiful but naturally see the child as one of many (Pitney 2015, p. 70). These meetings are often contentious and function as local battlegrounds for the implementation of IDEA on a case-by-case basis. Nearly all parents are at an IEP disadvantage compared to school districts (Pitney 2015). Whereas schools have the advantage of being repeat players in the system, generally having handled many cases in the bureaucracy and developed professional expertise on the subject, parents only have the experience of their own child (Pitney 2015) – creating an intimidating environment with a severe power imbalance.

It’s important to remember that local implementation battles between parents and schools are impacted by the money clashes between stakeholders higher up in the system. Within education services, the “theater of conflict is all about inter-governmental relations. States and localities are primarily responsible for education, but federal statutes set the rules of engagement” (Pitney 2015, p. 14). Complying with federal IDEA law comes at a large expense to states and school districts already under financial pressure – particularly when the federal government doesn’t fulfill its original promise to shoulder 40% of states’ “excess costs” to educate students with disabilities.

Variation Across the System

The US federalist system creates many partially autonomous venues for policy action, which encourages significant diversity in policy structures and outcomes (Baumgartner and Jones 1993). According to Professor John Pitney, there is always going to be variation in a federalist system, “but perhaps with autism, the variation is more extreme” (Pitney 2020). When it comes to transition services, “what you get from the government depends on where you live” (Pitney

2015, p. 64). Some schools have greater resources and are more likely to provide high levels of service to people with autism. Likewise, out-of-school services vary significantly state to state.

Subnational jurisdictions can be used as testing grounds for new ideas and policies, later to be mimicked if successful or abandoned if unworkable (Baumgartner and Jones 1993). For example, California's approach to providing out-of-school services for people with developmental disabilities bears recognition. Its structure relies upon 21 private, nonprofit regional centers contracted by California's Department of Developmental Services, which serve as middle men providing coordination between local service providers and clients and families who qualify for support – while offering some programming of their own (CA Department of Developmental Services 2020). Of particular note, the system is available to those who qualify from birth to death, providing a level of service continuity uncommon in many states, where transitioning between several service systems across the lifespan is common (Sullivan 2020).

Confronting Challenges and Cases of Success

The following case studies illustrate how different programs have responded to challenges in the system, finding innovative solutions to maximize success. The Cedarhurst School's Passage Program and the Uniquely Able Project aim to cultivate greater independence among autistic students while trying to provide the skills, experience, and training necessary to help them succeed in competitive employment. These are private, nonprofit programs striving to fill the gaps in the current transition system. Passage is a school-based service in Connecticut, while the Uniquely Able Project is a pre-employment program offered after high school in California.

The Cedarhurst School's Passage Program (Hamden, CT)

The Cedarhurst School is a private therapeutic junior and senior high school operated by Yale University, offering a structured, supportive learning environment to students identified as autistic,

emotionally disturbed, or having other health impairments, who are outplaced from school districts throughout Connecticut (Yale School of Medicine 2019). Cedarhurst's Passage Program specifically serves about a dozen special education students ages 18–21, creating an individualized pre-employment and independent living program attempting to support students in their transition to independence (Yale School of Medicine 2019). Student tuition is paid by the sending school district – with partial reimbursement from the state of Connecticut – and is estimated to be about \$75,000/year including school and transportation (Donovan 2020).

The transition-focused Passage Program, founded 10 years ago, was born out of a need among Cedarhurst students who were not ready to enter the real world, particularly when placed within a system that provided insufficient transition support after high school (Donovan and Clemens 2020). The program invests in on-site, community-based experiences, including daily part-time job placements at local businesses, and courses at nearby colleges including Southern Connecticut State University and Albertus Magnus College (Kannatt et al. 2020). These activities are supplemented by life skills and vocational classes at Cedarhurst, assistance in connecting students with state agencies that can provide additional transition services during and after Passage, and a weekly social skills group which develops peer-to-peer relationships between Passage students and a group of student volunteers at Yale (Kannatt et al. 2020).

Cedarhurst's expensive tuition and affiliation with Yale help enable the school's low student-to-faculty ratio and high standard of care, but unfortunately this makes the program quite difficult to replicate in public districts, which have fewer resources and struggle to provide adequate special education services. That being said, there are important lessons about transition to learn from Passage, including the program's:

- Individualization-heavy, community-centered model
- Daily job placements
- Private sector partnerships

- Efforts to coordinate services with local colleges and state agencies
- Peer-led social skills groups

The Uniquely Abled Project (Los Angeles, CA)

The Uniquely Abled Project (UAP) provides post-high school vocational opportunities to young adults with ASD, matching the unique skills of autistic individuals to high-demand career jobs, in a way that is scalable and free to parents. Founder Ivan Rosenberg, a management consultant and parent of two children on the spectrum, saw himself as a “business person dealing with a social problem” – confronting two major challenges he believed could become solutions for each other: (1) the soaring unemployment rate for millions of Americans with disabilities and (2) the fact that many businesses lack access to a skilled workforce (Rosenberg 2020).

Rosenberg identified several barriers related to the unemployment problem:

- Use of the word “disabled”
- Lack of understanding among employers and job developers regarding the potential of people with autism
- Insufficient affordable, vocational education programs for people with ASD
- Scarce efforts to match unique abilities to the specific needs of jobs (Rosenberg 2020)

UAP works within existing education and employment systems to create a structure of collaboration between different stakeholders – including autistic employees, educators at community colleges, job developers at state agencies, autism specialists, and private employers – under the banner of a single program. Its 16-week academy comprehensively trains, places, and provides ongoing support to individuals with ASD by (1) matching diagnoses to jobs, (2) offering vocational and soft skills training through community colleges, (3) teaching instructors how to train autistic students, (4) educating job developers to find specific manufacturing jobs students are being trained for, (5) coaching employers on how to work with autistic employees, and (6) providing post-hire support to academy students (Rosenberg 2020).

UAP provides consulting and facilitates collaboration to get programs started in different locales. The academy’s first major job match has been between people with high-functioning autism, who are often good at repetitive work with clear instructions, and entry-level computerized machine operator jobs in the manufacturing industry. To date, it has been quite successful, with an estimated 69 machine operator job placements out of 70 graduates since August 2016 (Rosenberg 2020). Because UAP works within the existing community college and employment agency systems, the cost of the program is low – about \$3,000–5,000 per student, which is subsidized by regional centers, state agencies, and banks (Rosenberg 2020). UAP plans to expand its approach and business model to assist more challenged autistic individuals while diversifying to other industries.

Several lessons can be learned from UAP’s:

- Comprehensive, collaborative training model within existing systems
- Identification of high-demand jobs that match with unique abilities of ASD individuals
- Desire to empower abilities of people with ASD within a culture of high expectations
- High placement rate, low cost, and potential for scalability

Relative success stories can often be attributed to resource access and money; however, innovative ideas, cross-sector collaboration, effective employer outreach, and a culture of high expectations also play a significant role. Although the autistic young adults participating in these two programs are predominantly “high-functioning” on the spectrum, several lessons and themes regarding the broader transition services system can be distilled. It is critical to generalize best practices from successful organizations to the larger autistic population – otherwise, only a select few will benefit.

Shaping the System from the Ground Up: Mobilization Among Parents

Parents are one of the stakeholders closest to the transition issue and most frustrated by its

challenges. However, the service system is set up in a way in which it can be difficult for them to effectively mobilize politically. Autism is a time-consuming and exhausting condition for both parents and individuals directly affected, which means there is often little energy for political advocacy and lobbying (Pitney 2015). Moreover, it can be hard to mobilize within schools because the entire nature of the IEP creation and implementation process is individual and private. But these factors haven't stopped many parents from advocating and creating service programs for this population, particularly with the rise of new electronic platforms like social media and mass mailing lists. The past 10–15 years has seen an increase in parent-initiated services that help fellow parents navigate the complex world of autism and create opportunities for individuals in need of vocational training or jobs. Additionally, many parents have leveraged their knowledge to become paid advocates, spawning a new employment sector providing a less expensive alternative to lawyers.

Future Directions

Policy Recommendations: Enhancing Autism Transition for a Brighter Future

1. *Further invest in quality of life research, and study transition program and employment outcomes, in order to better understand where major service gaps lie – and what programs actually work.*

Much of the confusion and uncertainty characterizing autism transition is the result of lacking adult outcome research and unanswered questions about the long-term impacts of programs, services, and other interventions. A 2012 review of nearly 150 articles on autism intervention research found less than 2% of participants over age 20, while another study assessing papers on adults with autism published from 2000 to 2010 found only 23 out of 11,000 studies directly addressing intervention services (Howlin 2014). Without this research it is difficult to measure the performance and enhance the quality of transition

services most effective at improving the lives of autistic people while creating policies that help to facilitate the creation thereof. While conducting long-term outcome and transition research, it is critical to include the input of autistic individuals.

2. *Require the federal government to fulfill its original obligation to cover 40% of a state's "excess costs" to educate children with disabilities through IDEA.*

Many of the money clashes and implementation battles challenging the transition services system – particularly within the education sphere – result from a lack of federal financial commitment to the Individuals with Disabilities Education Act. When the original legislation was signed in 1975, the drafters didn't anticipate the extent of the cost that would be placed on school districts or the complex services that would be needed to support students with more "invisible disabilities" like autism. Now that the government is aware of these challenges, it is time to reassert its commitment. A significant portion of this increased federal special education spending should be allocated to transition services and accompanied by more specific and ambitious guidelines related to the creation of IEPs and ITPs.

3. *Teach autistic individuals generalizable, community-based vocational and social skills – corresponding to their unique abilities and high demand jobs – both while in the education system and afterward.*

The education system and out-of-school service providers can learn lessons from case studies on the Cedarhurst School and the Uniquely Abled Project. Cedarhurst's Passage Program recognizes the need to find individualized, community-based job placements for students with special needs based on their interests and abilities – providing them with real-life skills that can be generalized to jobs after school ends. Meanwhile, UAP illustrates the importance of continuing to develop these vocational skills – within a culture of high expectations – once IDEA entitlements run out. UAP embodies the success that can

be associated with retro-engineering training programs to match the unique abilities of autistic individuals with the specific needs of high-turnover jobs. These programs recognize the need to accompany vocational training with the strengthening of social skills, in order to help overcome major barriers related to an autistic person's ability to be hired.

4. *Enhance collaboration between school districts, state and private programs, and employers in a way that reduces the post-IDEA services cliff, helps families navigate the system, and holds autistic adults to a higher set of expectations.*

A lack of collaboration between the various entities with a stake in the autism transition process heightens the presence of the services cliff and contributes to the challenges families face in navigating the complexities of the transition and adult service systems. Much of the confusion and clashes of values associated with insufficient collaboration are a result of political and policy fragmentation and stigma toward autistic adults. While the education system provides an infrastructure to support autistic individuals until age 21, no such logical system exists afterward. Ultimately, it may be beneficial for states to invest in autism-specific coordinating committees, aimed at helping to build partnerships between the business community, school districts, and state and private programs. Responsibilities could include the development of comprehensive lists of statewide programs available for people with autism and the creation of employer training modules to enhance autism awareness in the business community.

Transitioning to adulthood is not easy for anyone. It involves new, often daunting responsibilities, difficult decisions, and changes in environments. It is particularly challenging for the large group of autistic young adults aging out of the education system, facing a dizzying transition services system that is insufficient in supporting their potential and capitalizing on their unique abilities. The unexpected circumstances presented by the COVID-19 pandemic

pose particularly intense challenges for many on the spectrum, who do not deal well with a lack of structure or widespread uncertainty. With rising unemployment and looming budget cuts, there are legitimate concerns about what the future of an already-neglected autism transition service system will look like. For these reasons, it is particularly important to continue studying this problematic facet of autism politics and policy, in order to better understand how it works, why it is challenged, and how it can be improved.

Historical Background

At a time when Portuguese psychiatry was strongly dominated by the psychoanalytic school, parents' associations played a decisive role in the struggle for the implementation of clinical and pedagogical approaches to autism in Portugal.

As a matter of fact, it can be said that the popularization of autism recognition in Portugal was largely due to the commitment of parents.

In 1971, the first autism-specific institution, the Portuguese Association for the Protection of Autistic Children (APPCA), was founded in Lisbon, by a group of parents who did not find educational responses for their children with autism. This group was led by the physician and father, Dr. José Carlos de Almeida Gonçalves. APPCA's main objective was to build up a school where the specific needs of their children with autism could be met. The educational structure and model was created with the support from therapists of the British National Society for Autistic Children (NSAC), now the National Society for Autism (NSA), with whom the founders of APPCA had close contact since the beginning of the project. In 1972 the first clinical and therapeutic center for autism spectrum disorders was created by APPCA, in Lisbon. In 1984, the APPCA created a delegation in the north of Portugal, in Vila Nova de Gaia, where a second center was later to be opened. As a result of this process, and considering that the APPCA started to support not only children but adolescents and adults as well, the name was turned to

Portuguese Association for the Protection of Autistic Persons (APPDA), and the structure became decentralized: a national association with delegations in Lisbon and the North. Other delegations were later to be established in the center and south of the country and in Madeira and Azores islands. The APPDA is a member of the Autism-Europe International Association since 1988. The commitment of APPDA's President, Isabel Cottinelli Telmo, was pivotal for its development during that period. She was Vice-President of Autism-Europe from 1990 to 2008.

These associations were initially geared toward supporting people with very little autonomy and very low social skills. In 2003, the Portuguese Association of Asperger Syndrome (APSA) was created to try and meet the needs of people diagnosed with autism spectrum disorder (ASD) with greater functionality.

Some of these associations in the north, center, and south of the country have now special-needs schools, occupational centers, medical and psychology consultations, training centers, and residential support.

In 2002, the APPDA split up into as many autonomous associations as the existing regional delegations, under the common denomination of APPDA – Portuguese Association for Developmental Disorders and Autism. Together with a few other associations devoted to autism, these formed the Portuguese Autism Federation (FPDA), based in Lisbon.

Within the scope of the National Health Service, the diagnosis and intervention in Autism were carried out by the child and adolescent psychiatry and the neuropsychiatric and developmental pediatrics departments located in the main central hospitals. The first clinical and psychological interventions were also based in these same departments. In the late 1990s and early 2000s, with the pioneering drive of a few department directors, the creation of specific child development centers in the main central hospitals (in Lisbon, Porto, Coimbra, and Almada) was assured. These are centers within the National Health Service that provide services for prevention, diagnosis, and treatment of developmental disorders.

In 1999/2000, the first nationwide epidemiological study of autism was carried out on the population of Portuguese school children aged 6–9 years old (Oliveira et al. 2007).

Legal Issues, Mandates for Service

The specificity of autism spectrum disorders (ASD) was recognized by the Law decree 3/2008, which established the creation of “structured teaching units” which adapted specific methodologies and organizational practices to children and adolescents with autism. These units were to be created in public schools according to a policy of inclusive education.

Decree 21/2008 came afterward, recognizing the importance of special education schools for children with very little autonomy and severe behavioral problems. Referral to these later schools follows a case-by-case evaluation process.

With regard to the diagnosis and referral of children with alleged ASD, it is usually done by the pediatrician or the general practitioner. The initiative may also come from parents, teachers, or other therapists who attend the child. The referral is made to specialized services (Child and Adolescent Psychiatry, Neuropsychiatric, Developmental Pediatrics) or to the child development centers. These services are available both in the National Health Service and in private clinics.

Eligibility for support is achieved through evaluation by a Social Security Medical Board. The levels of support made available vary according to the degree of disability recognized. The level of support can vary throughout life, according to new assessments.

Overview of Current Treatments and Centers

Preschool intervention is ensured through National Health Service multidisciplinary teams (“early intervention” teams) linked to National Health Service centers or in private clinical centers specializing in intervention in developmental disorders. Some of these are nonprofit institutions.

During school age (6–7 years old), children with autism are mostly integrated in regular education schools. Whenever possible these children are referred to the so-called Structured Teaching Units (STU). These are special education units, based in regular schools, that implement teaching methodologies adapted to children with ASD, namely, the TEACCH (Treatment and Education of Autistic and Related Communication Handicapped Children) methodology. Its regulation was made by Law decree 3/2008. Pursuant to Article 30 of the Law decree 3/2008, partnerships were established with specialized resource centers, namely, to carry out specific programs, improve education strategies, and start preparing the transition to adulthood.

In cases where children have very little autonomy, or severe behavioral problems, they can be referred to special education schools.

Some centers offer specific intervention programs (e.g., DIR Floortime, applied behavior analysis (ABA)). Several other complementary and alternative treatments have been publicized and eventually used but generally with limited adherence.

After compulsory schooling, people with autism having good autonomy are, whenever possible, oriented toward professional employment (sometimes supported by protected employment or supported employment structures). People with reduced autonomy are oriented to specialized centers, where multidisciplinary interventions and occupational activities are implemented. Some of these have also associated residential structures.

Overview of Research Directions

The country's major research centers endorsing autism research programs are connected to universities or, in some cases, to neuroscience research centers inside private, nonprofit foundations. The main centers of research in autism are located in Coimbra and Lisbon.

The research developed at these centers has been oriented mainly toward basic genetic mechanisms (Coutinho et al. 2007; Correia et al. 2009)

and cell biology (Oliveira et al. 2005), neuropsychological characterization of ASD (Carmo et al. 2016, 2017), adaptive behavioral profiles (Mouga et al. 2015, 2016), and neurophysiology (Amaral et al. 2015; Tavares et al. 2016).

Some of these centers have also had an active participation in international consortia (Pinto et al. 2014; Salomone et al. 2016).

Overview of Training

The training is done in two different moments: undergrad and postgrad professional training. Different professional courses and university courses, namely, in psychology, psychomotricity, and teaching, consider in their curricula disciplines in which PEA is loomed. Posterior training is implemented in the centers devoted to autism that promote specific training and in-job training, under the guidance of supervisors with experience in Autism.

Definition

Positive behavior support (PBS), also referred to as positive behavioral interventions and supports (PBIS), is a multitiered data-driven system of support, assessment, and intervention which has a potentially broad application base. Positive behavioral interventions and supports incorporate both academic and social interventions to promote overall competence. PBIS systems and procedures utilize empirically based decision-making

to support appropriate behaviors and successful student outcomes. Over the past decades, the research-based practices characteristic of PBIS have been shown effective in promoting a positive school climate and the prosocial behaviors which are important for success later in life (Gage et al. 2015). School-wide positive behavior support (SWPBS) has grown in popularity in both special and general education settings. Studies have shown improved outcomes for schools which implement this system with fidelity (Simonsen et al. 2012). More recently, data suggests that PBS could be helpful in other alternative settings (Simonsen and Sugai 2013; Farkas et al. 2012).

Positive behavioral interventions and supports uses a continuum approach and therefore contains systems and procedures which are flexible enough to meet the varying needs of individuals as well as provides an infrastructure of supports for larger organizations or groups. This increasingly popular collaborative and comprehensive prosocial model began as a non-aversive applied behavioral analysis-based special education intervention. PBS has been continuously evolving over the past 35 years.

Positive behavior support has recently been redefined by Kincaid et al. (2016):

PBS is an approach to behavior support that includes an ongoing process of research-based assessment, intervention, and data-based decision-making focused on building social and other functional competencies, creating supportive contexts, and preventing strategies that are respectful of a person's dignity and overall well-being and that are drawn primarily from behavioral, educational, and social services, although other evidence-based procedures may be incorporated. PBS may be applied within a multitiered framework at the level of the individual and at the level of larger systems (e.g., families, classrooms, schools, social service programs, and facilities) (p. 71).

Historical Background

Positive behavior support emerged in the 1980s as a direct result of the disability civil rights

movement. The concomitant deinstitutionalization of the disabled brought with it a need to manage behavioral issues at home, in the community, and at school. P.L. 94–142, the Education for All Handicapped Children Act (1975), mandated a free appropriate public education (FAPE) for all children regardless of disability. Consequently, families and local school districts were now required to figure out how to overcome behavioral challenges, comply with the new education laws, and accommodate children with disabilities.

At that time, applied behavioral analysis and its aversive therapies were the dominant approach for professionals to remediate problematic or challenging behaviors of students with disabilities. Negative reinforcement therapies, such as electric shock or other painful treatments, were controversial, but many medical professionals accepted these practices for their utility and effectiveness. In the 1960s, Lovaas's work demonstrated that the behavior of autistic children with severe communication issues could be modified by administering consequences. Lovaas advocated both positive reinforcement and more controversially contingent aversives, if necessary. He was an early advocate of using applied behavior analysis interventions for children with autism. His work showed that children with autism could be maintained at home or in a community setting (Smith and Eikeseth 2011).

The general public was not ready to tolerate harsh aversive practices in the community. Functional analysis was developed as an alternative to punishment and consequence-based behavior modification (Dunlap et al. 2009). This positive-based and non-aversive option to control difficult behaviors was welcomed by both parents and professionals to maintain disabled youth in both community and educational settings. Positive behavior supports uses functional analyses to examine and problem solve challenging behaviors. Evidence-based interventions and strategies are employed to support improved student outcomes and decrease incidences of inappropriate behavior. Functional behavioral analysis (FBA) has evolved into a process of understanding the primary function and underlying conditions of a problematic behavior. Data collection and

subsequent hypotheses help to determine the best way to reduce an undesirable behavior. Several recent studies have shown evidence that using the FBA process is an effective intervention for individuals with autism spectrum disorders from toddler through young adult (Fettig 2013).

The momentum of the positive behavior support movement was reinforced in the 1990s, with the amendment of P.L. 94–142, as the Individuals with Disabilities Education Act (IDEA) of 1997. The reauthorization of this special education law explicitly named positive behavioral interventions and supports (PBIS) as an effective school-wide approach to manage student behaviors (National Education Association 2014). More recently, P.L. 108–446, the Individuals with Disabilities Education Improvement Act of 2004, requires that all students receive free appropriate public education in the least restrictive environment (LRE).

Through the years, Congress has amended the IDEA (1997) and IDEIA (2004) with the goal of supporting students with both developmental and emotional difficulties. This legislation mandates schools use empirically supported practices to address social and academic behaviors which might interfere with a student's overall learning and success at school. The utilization of positive behavior support's preventative, prosocial, and empirically grounded elements, such as functional behavioral assessments (FBA) and behavioral intervention plans (BIP), and identification of measurable goals within an individualized education plan (IEP) is supported by this groundbreaking legislation. (www.pbis.org/school/pbis-and-the-law).

Federal grants have led to continued support for the development and evolution of the positive behavioral interventions and supports movement. The national positive behavior interventions and supports (PBIS) technical assistance center is maintained by the US Department of Education's Office of Special Education Programs (OSEP). This Center is staffed by researchers from the University of Oregon and the University of Connecticut. Professional training and implementation materials are free and readily available on the comprehensive website, PBIS.org. Procedures to monitor and support fidelity in the

implementation of positive behavior supports are provided by OSEP. The PBIS technical assistance center also maintains a computer application which provides a mechanism to support data collection in school-like environments for a nominal yearly fee. Organizations are also asked to complete surveys and continuously assess the progress and integrity with which they are adapting the PBIS framework. These assessment tools are available for organizations on the PBIS.org website. The fidelity of application is a key factor to consider when measuring the success and impact of the PBIS approach (Farkas et al. 2012).

Current Knowledge

Initially, positive behavior support was instituted in schools to address students with emotional and behavioral disorders. However, it was soon realized that positive behavior supports could be helpful for all students. The positive behavior preventative approach includes a strong interest in positive outcomes for individuals while maintaining respect for their dignity. Researched practices which promote social and academic success have been incorporated into the positive behavior approach framework. The current social service movement toward person-centered planning and self-determination works well within this approach. According to Horner (2013), more than 19,000 schools in the United States have trained their staff in school-wide positive behavior interventions and supports (SWPBIS) since 2000. The popularity of positive behavior support in schools does vary by state. For example, there are three states which have 60% of their schools following positive behavior support, and 16 states have greater 30% of their schools utilizing SWPBIS (Sugai and Simonsen 2012).

Positive behavioral interventions and supports focuses on supporting all students by creating a universally positive climate, utilizing research-based best practices both inside the classroom and outside the classroom, and examining the function of behaviors to identify appropriate individualized interventions. Positive behavior supports is data based, and decision-making is based

upon reported behaviors and systems for continued evaluation of outcomes. Mechanisms for the collection and analysis of behavioral data to assess the effectiveness of a selected approach are an important characteristic of positive behavior supports. The examination of student (s) response(s) to intervention(s) allows staff to modify their approach, when needed. The three-tiered continuum approach of positive behavior supports gives flexibility to address issues which impact an entire organization, a subgroup of the organization with a common behavioral issue, or, if needed, individual students. More support, intensive intervention, or skill development can be added, if deemed necessary. There are also several tools to aid organizations in monitoring and assessing their overall fidelity in implementing the positive behavior support approach. The positive behavior supports framework usually takes between 3 and 5 years to become fully functional in an organization.

The positive behavioral interventions and supports approach encompasses three integrated tiers which emphasize prevention by teaching, reteaching, and praising expected behaviors on a continuum. The tier one foundation of positive behavioral intervention and supports continuum approach supports the universal communication of a school-wide culture. This “code of conduct” clearly operationalizes positively stated prosocial values. Positive behavior supports seeks to teach all students how to behave by establishing standards of behavior across various settings. By teaching, reteaching, and reinforcing appropriate behaviors, schools improve the learning environment. By improving the school’s overall climate, the hope is to increase overall student achievement.

The connection between socio-emotional competence and academic achievement has been documented (Farkas et al. 2012). The explicit delineation of expected behaviors is particularly helpful to students with autism spectrum disorders who tend to have difficulty recognizing social cues or picking up on social norms in different settings. The concrete existence of positively stated expectations and rules guides students toward being better able to navigate toward more appropriate behaviors. The provision of

recognition and rewards to those students who meet or exceed stated standards serves to further reinforce appropriate behaviors. The consistency of language and predictable responses also works well for students with autism spectrum disorder. Common examples of this “code of conduct” might include “be responsible,” “be safe,” and/or “be respectful.” Specific descriptions, posters, or role plays around exactly “what this value looks like” are part of the PBIS teaching and reteaching component and are embedded into the curriculum across various settings.

The tier 2 of the positive behavioral interventions and supports continuum approach supports subgroups of students who need additional skill building in an area. A variety of interventions which can exist as part of the school’s available extra supports could be implemented. An example of such an intervention could be a social skill group, a check in/check out, or a study skills group. These groups would typically break down the steps of the required skill and provide opportunities for students to practice these skills. Staff would be trained in leading and monitoring these interventions. Data-based decision-making would determine the effectiveness and duration of participation in these interventions.

Tier 3 of the positive behavioral interventions and supports continuum approach provides more individualized plans for students who require more specific and intensive supports to meet behavioral expectations. At this level, functional behavioral assessments and behavioral intervention plans are important to identify which student needs, the inappropriate behavior is meeting (usually to obtain or to escape). A specific plan to discourage and replace the problematic behavior would be developed. The plan would need to be communicated and implemented across the whole organization for consistency. Family involvement and feedback can also be valuable.

Functional behavioral assessments consider behaviors from a more ecological perspective with an emphasis on prevention. Positive behavioral interventions and supports encourages the use of functional behavioral assessments at all tiers to analyze problems by understanding the

behavioral pathway. The behavioral pathway examines not only the problematic behavior but also the specific circumstances and environments under which the behavior occurs. By examining the behavioral pathway, interventions consider intrapersonal, interpersonal, environmental, and systemic factors. Preventative measures and additional supports can be instrumental in addressing factors leading up to the problematic behavior such as setting events, triggering antecedents, and maintaining consequences. The functional behavioral assessment shifts the focus from the behavior to the function of the behavior. The purpose is to identify a more acceptable replacement behavior which serves the same function as the unacceptable behavior.

Youth with autism and other developmental disorders may exhibit behaviors which interrupt the educational process and negatively impact their academic performance. The goal of positive behavior supports is to promote social competence, increase appropriate behaviors, and therefore encourage both social and academic achievement. The collaborative team and school-wide nature of this framework approach promote consistency and continuity and therefore would work well in meeting the needs of students with autism spectrum disorder (ASD) who benefit from structure, routine, and repetition. The transparency of expectations could also lower the stress level for individuals with ASD who do better when they can predict their environment (LaVoie 2005). Engaging families in the positive behavioral interventions and supports process is also an important component of setting students up for success.

As students progress through school and begin to transition toward adulthood, they are increasingly required to be accountable in managing their time and schedule. Positive behavioral interventions and supports usually promotes the prosocial value of being responsible. Research-based interventions which have been proven effective in promoting executive skill management, such as modeling, prompting, reinforcement, social skills training, etc., can all be embedded as interventions within the many tiers of the PBIS framework (Wong et al. 2013).

Future Directions

Positive behavioral interventions and supports is a very dynamic concept which is continually evolving. A wide array of literature provides empirical support for school-wide positive behavior supports as helpful to all students (Horner et al. 2010). Findings have associated school-wide positive behavioral interventions and supports with a more positive school environment, decrease in incidences requiring disciplinary actions, and improved academic achievements (Farkas et al. 2012).

States have been providing technical assistance to support the training and assistance to schools helping them to accurately implement all three tiers of PBIS. An integral part of positive behavior supports is the structure and designation of trained leadership teams who guide and support its adaption. School staff members are integral to the continuity and success of the implementation process. Data indicate significant positive outcomes when positive behavior supports is implemented correctly (Gage et al. 2015). There are several ways to evaluate the fidelity of implementation at each tier. A vast majority of states provide support for PBIS at either the district or state level to implement tier 1. However, the more specific training required and additional resources necessary to correctly implement tier 2 and tier 3 with fidelity make its successful adaptation more difficult (Pas and Bradshaw 2012). With so many variables to research within the positive behavior interventions and supports framework, the critical impact of each factor and stage of implementation on the effectiveness of PBIS need further research to be clarified (Childs et al. 2016).

The mandate for schools to use data-based methods to ensure a free and appropriate education for all has spurred research on best practices. The connection between academic achievement and social success is crucial. Positive behavior supports was originally developed for use in general education settings. Its success has led to consideration of instituting this framework in alternative organizations such as residential settings, psychiatric hospitals, mental health,

juvenile correction, day treatment programs, or transition programs. Implementation efforts in schools which only serve students with significant disabilities also need to be evaluated (Schelling and Harris 2016).

Several recent high-profile instances of violence in schools have expanded interest in addressing mental health issues for children in schools. According to Gage et al. (2015), PBIS has been associated with improved school climate and a reduction in disciplinary procedures such as out-of-school suspensions (Gage et al. 2015). The No Child Left Behind Act (2001) includes an emphasis on addressing issues of student well-being. Future directions to improve student well-being should look at the possible development of “wraparound” collaborations between the positive behavior support framework in educational settings and mental health organizations (Anello et al. 2016).

Future directions include the consideration of adapting positive behavior support systems within alternative programs (Simonsen and Sugai 2013). More studies and research are needed to establish the effectiveness of PBIS in alternative settings (Farkas et al. 2012). P.L. 110–315, the Higher Education Opportunity Act (HEOA) of 2008, establishes better access for students with intellectual disabilities to postsecondary education. Research should be conducted to consider how to adapt the positive behavior supports model in college settings.

Positive Behavioral Support

Erik Bromberg
University of California, Santa Barbara, Santa
Barbara, CA, USA

Synonyms

Positive behavior intervention; Positive behavior support

Definition

Positive behavioral support is both a values-based and an empirically verified system that uses specific nonaversive procedures to improve an individual's quality of life as well as reduce their problem behaviors in community settings. Positive behavioral support procedures were developed from the literature of applied behavioral analysis and operant conditioning and were created in response to the concern over the possible detrimental effects of aversive behavioral interventions on a person. Positive behavioral support

comprises varied treatment methods including pivotal response treatments; however, there are themes central to all techniques. One, functional analysis is used to identify both the context as well as the adaptive function of the problem behavior. Two, the intervention provides behavioral change while minimizing the use of punishers. Three, the use of the intervention is justified by the outcome. Four, the intervention considers the ecological context of the behavior. Five, the intervention is socially valid and respectful of a person's dignity.

Positive reinforcement is defined as the presentation of a stimulus contingent on a behavior that results in an increased frequency of that behavior in the future. The reinforcing stimulus is strongest if it is presented immediately following the behavior. For example, if a child with autism is told to sit in a chair and receives a desired treat such as a candy immediately after sitting, the likelihood of the child sitting down more frequently in the future increases. The effect of reinforcement depends on the strength of the reinforcer being used. However, procedures are also available for using delayed or partial reinforcement schedules. Strong reinforcers are idiosyncratic and depend on the individual as well as the environmental context, availability of other reinforcers, etc. Commonly used reinforcers include edibles, activities, praise, and tangibles such as toys or stickers.

Child Study Center, Yale University School of
Medicine, New Haven, CT, USA

Synonyms

[PET](#)

Definition

Positron-emission tomography (PET) is an imaging technique from the field of nuclear medicine. The technique produces a three-dimensional image or picture of functional processes in the body including the brain. The technique involves the use of a detector to measure pairs of gamma rays emitted indirectly by a positron-emitting radionuclide (tracer), which is introduced into the body on a biologically active molecule. Three-dimensional images of tracer concentration within the body are then constructed by computer analysis. With this technique, it is possible to image brain function and its disruption in neuropsychiatric and neurodevelopmental disorders. Because the technique involves ionizing radiation, it is not typically used in research studies of children.

Short Description or Definition

Posttraumatic stress disorder (PTSD) is a disorder characterized by specific symptoms which can develop after exposure to a potential traumatic event (PTE) or a number of traumatic events. PTEs in the general population may involve rape, motor vehicle accidents, assault, natural disasters, or terrorism. In the military, war zone or peacekeeping exposure – including imprisonment, torture, or witnessing atrocities or comrades being wounded or killed – might serve as a significant traumatic event. In PTSD, the individual will relive the traumatic event through intrusive thoughts and recollections during the day or disturbing dreams at night. When triggered by reminders, individuals often become emotionally upset and exhibit physical symptoms of anxiety. They will often avoid thinking and talking about their traumatic event or avoid specific reminders that trigger distress. Individuals may suffer from persistent negative

beliefs and emotions, lose interest in previously pleasurable activities, and feel detached from others. They generally also display hyperarousal symptoms including difficulty sleeping, poor concentration, irritability, hypervigilance, and being easily startled.

Categorization

PTSD is classified as a trauma-and-stressor-related disorder under the *Diagnostic and Statistical Manual of Mental Disorder* (American Psychiatric Association [APA] 2013). PTSD is unique among psychiatric diagnoses because of the requirement of a traumatic event in order to make the diagnosis. The traumatic event involves exposure to actual or threatened death, serious injury, or sexual violence. In order to meet the criteria for the “traumatic event,” exposure must occur by directly experiencing the traumatic event, witnessing the event occur to others, learning that the traumatic event occurred to a close family member or friend, and/or experiencing repeated or extreme exposure to aversive details of the traumatic event (Criterion A). Symptoms of PTSD are grouped in four main symptom clusters: reexperiencing, avoidance, negative alterations in cognition and mood, and hyperarousal. In addition to meeting the traumatic stressor criteria, the individual must present with at least one intrusive reexperiencing (Criterion B) symptom where the individual will relive the traumatic event in intrusive thoughts and recollections, one or both symptoms of avoidance (Criterion C), at least two symptoms of negative cognitions and moods (Criterion D), and at least two symptoms of hyperarousal (Criterion E). Finally, to make the diagnosis, the individual exposed to the traumatic event must experience significant impairment in social and/or occupational functioning as a result of their symptoms (Criterion G). According to DSM 5, the duration of the disturbance must be greater than one month (Criterion F) (American Psychiatric Association [APA] 2013) (Table 1).

Posttraumatic Stress Disorder, Table 1 Posttraumatic Stress Disorder, Diagnostic Criteria (excerpt from the DSM-5, pages 271–274). (Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders. Copyright 2013. American Psychiatric Association)

Note: The following criteria apply to adults, adolescents, and children older than 6 years. For children 6 years and younger, see corresponding criteria below.

A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s).
2. Witnessing, in person, the event(s) as it occurred to others.
3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event (s) must have been violent or accidental.

4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).

Note: Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work-related.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

Note: In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event (s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

5. Marked physiological reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event (s) occurred, as evidenced by one or both of the following:

1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

2. Avoidance of or efforts to avoid external

(continued)

Posttraumatic Stress Disorder, Table 1 (continued)

reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).

2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined").

3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others.

4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).

5. Markedly diminished interest or participation in significant activities.

6. Feelings of detachment or estrangement from others.

7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.

2. Reckless or self-destructive behavior.

3. Hypervigilance.

4. Exaggerated startle response.

5. Problems with concentration.

6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

F. Duration of the disturbance (Criteria B, C, D, and E) is more than 1 month.

G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The disturbance is not attributable to the physiological effects of a substance (e.g., medication, alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

(continued)

Posttraumatic Stress Disorder, Table 1 (continued)

1. **Depersonalization:** Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).

2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Specify whether:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Posttraumatic Stress Disorder for Children 6 Years and Younger

A. In children 6 years and younger, exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s).

2. Witnessing, in person, the event(s) as it occurred to others, especially primary caregivers.

Note: Witnessing does not include events that are witnessed only in electronic media, television, movies, or pictures.

3. Learning that the traumatic event(s) occurred to a parent or caregiving figure.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

Note: Spontaneous and intrusive memories may not necessarily appear distressing and may be expressed as play reenactment.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: It may not be possible to ascertain that the frightening content is related to the traumatic event.

3. Dissociative reactions (e.g., flashbacks) in which the child feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.) Such trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

5. physiological reactions to reminders of the traumatic event(s).

(continued)

Posttraumatic Stress Disorder, Table 1 (continued)

C. One or more of the following symptoms, representing either persistent avoidance of stimuli associated with the traumatic event(s) or negative alterations in cognitions and mood associated with the traumatic event(s), must be present, beginning after the event(s) or worsening after the event(s):

Persistent Avoidance of Stimuli

1. Avoidance of or efforts to avoid activities, places, or physical reminders that arouse recollections of the traumatic event(s).

2. Avoidance of or efforts to avoid people, conversations, or interpersonal situations that arouse recollections of the traumatic event(s).

Negative Alterations in Cognitions

3. Substantially increased frequency of negative emotional states (e.g., fear, guilt, sadness, shame, confusion).

4. Markedly diminished interest or participation in significant activities, including constriction of play.

5. Socially withdrawn behavior.

6. Persistent reduction in expression of positive emotions.

D. Alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects (including extreme temper tantrums).

2. Hypervigilance.

3. Exaggerated startle response.

4. Problems with concentration.

5. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

E. The duration of the disturbance is more than 1 month.

F. The disturbance causes clinically significant distress or impairment in relationships with parents, siblings, peers, or other caregivers or with school behavior.

G. The disturbance is not attributable to the physiological effects of a substance (e.g., medication or alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

1. **Depersonalization:** Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).

2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world

(continued)

Posttraumatic Stress Disorder, Table 1 (continued)

around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Specify whether:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Epidemiology

Exposure to a PTE is common: approximately 75.7% of individuals are exposed to a traumatic event sufficient to cause PTSD. However, not all individuals exposed to a traumatic event develop PTSD. The National Comorbidity Survey in the United States reported PTSD rates of 3.5% (12-month) and 6.8% (lifetime) (Kessler et al. 1995). PTSD rates are higher in women; the National Comorbidity Survey demonstrated prevalence rates of 10% in women and 5% in men (Kessler et al. 1995). In Canada, the lifetime prevalence of PTSD is similar to that found in the United States. In a community study in Canada, prevalence rates of PTSD were 2.4% (current and 1-month) and 9.2% (lifetime) (Van Ameringen 2003).

In veteran and military populations, the current and lifetime prevalence of PTSD among serving Canadian Armed Forces members has been estimated at 2.8% and 7.2%, respectively (Statistics Canada 2002). In a sample of Canadian peacekeeping veterans pensioned with a medical condition, 1-month prevalence of probable PTSD was reported as 10.3% (Richardson et al. 2006). In samples of US military members following deployment to Iraq and Afghanistan, the rates of PTSD were estimated between 11.2% and 17.1%, compared to a baseline rate of 5% before deployment (Hoge et al. 2004); while in a sample of UK military members, the reported rates were significantly lower at 4.8% (Iversen et al. 2009).

Natural History, Prognostic Factors, Outcomes

In general, the posttraumatic stress symptoms which might appear following exposure to a PTE are generally considered to be a normal response. In most individuals, the symptoms gradually subside and do not cause significant long-term impairment. However, if the symptoms persist and cause significant impairment in social and/or occupational functioning, then it is considered a disorder. Individuals who develop PTSD do not acquire new symptoms; rather, the initial posttraumatic stress symptoms which presented following the traumatic event do not subside.

Many risk factors have been identified for PTSD and are generally divided into pretraumatic, peritraumatic, and posttraumatic factors. Understanding risk factors is important in order to better identify and screen those who might be at increased risk of developing PTSD following exposure to a traumatic event. Pretraumatic risk factors include a family and/or personal history of psychiatric illness and past trauma including history of childhood abuse (Brewin et al. 2000; Ozer et al. 2003). Gender is another risk factor; although women are more likely to develop PTSD, men are more likely to be exposed to a traumatic event (Breslau et al. 1998; Kessler et al. 1995). Other pretraumatic risk factors include younger age, single marital status, and lower socioeconomic status (Breslau et al. 2006; Richardson et al. 2007). Peritraumatic risk factors include trauma severity and life threat (Brewin et al. 2000; Hoge et al. 2004; Richardson et al. 2007), and bodily injury (Koren et al. 2005). Peritraumatic risk factors specific to military-related PTSD include the number of operational deployments (Dohrenwend et al. 2006; Hoge et al. 2004; Richardson et al. 2007; Statistics Canada 2002). Finally, posttraumatic risk factors may include lack of access to treatment, stigmatization, ongoing life stressors, and lack of social support (Brewin et al. 2000; Ozer et al. 2003; Yehuda et al. 1998). Shame and guilt for developing PTSD symptoms are also posttraumatic risk factors (Yehuda et al. 1998).

Although the majority of people with posttraumatic stress symptoms will recover without treatment, a notable proportion will present with

significant persistent symptoms of PTSD, resulting in distress and/or impairment in functioning. As such, these individuals stand to benefit from treatment. Although not always possible, complete remission can be achieved in 30–50% of cases of PTSD (Friedman 2006). Pharmacological interventions, in addition to psychotherapy, can assist with symptom reduction and improve functioning and quality of life.

Clinical Expression and Pathophysiology

Clinically, PTSD rarely occurs on its own. Over 90% of individuals with PTSD meet criteria for at least one other mental disorder. Comorbidity is the rule rather than the exception. The most common comorbid disorders are major depressive disorder; anxiety disorders (social phobia, generalized anxiety disorder, obsessive-compulsive disorder, and panic disorder); and alcohol and substance use disorders (Kessler et al. 1995). Less common comorbid disorders are bipolar disorder and personality disorders, especially borderline (Pagura et al. 2010) and antisocial (Sareen et al. 2004). It is critical that these disorders be diagnosed as they complicate the clinical picture and can compromise treatment. There is also emerging evidence demonstrating a strong relationship between PTSD and physical health problems (Jakupcak et al. 2008; Sareen et al. 2007). The most common medical complaints associated with PTSD include chronic pain syndromes, mild traumatic brain injuries, asthma, gastrointestinal complaints, and cardiovascular disease (Sareen et al. 2005, 2007).

Although the exact neurophysiology of PTSD is not known, there are neurobiological alterations that have been implicated in PTSD including adrenergic hyperresponsiveness (Southwick et al. 1999), low cortisol levels, and enhanced negative feedback sensitivity of the hypothalamic-pituitary-adrenal axis (Yehuda et al. 1993; Yehuda et al. 2004), dysregulation of the immune response (Altemus et al. 2003; Raison and Miller 2003), and decreased hippocampal volume (Bonne et al. 2001; Bremner et al. 1995, 1997; Stein et al. 1997).

Evaluation and Differential Diagnosis

Important factors to consider in the differential diagnosis include prior exposure to psychological trauma and presence of any PTSD symptoms. As outlined above, patients with PTSD present with four symptom clusters: reexperiencing, avoidance, negative cognitions and moods, and hyperarousal symptoms (Canadian Psychiatric Association 2006).

PTSD symptoms and signs are generally non-specific, so initially the differential diagnosis of presenting symptoms may include both physical and mental disorders (Jetly and Cooper 2008). Check for physical, psychological, and social symptoms, inquire about exposure to psychological trauma, and then work through the differential diagnosis (Friedman 2006). While no physical health condition explains full-spectrum PTSD (Staab 2009), the condition may not be apparent initially, owing to avoidance or reluctance to discuss trauma-related events. Comorbid physical and mental health conditions are common in PTSD, and many have overlapping symptoms.

There are well-validated screens available for PTSD. Short screening instruments such as the Primary Care PTSD Screen, a four-item yes/no screening instrument, are designed for use by primary care practitioners. This screen has a sensitivity of 78% and specificity of 87% for PTSD in individuals who endorse three or more items (Friedman 2006). Individuals who screen positive should then be assessed for PTSD using the DSM 5 diagnostic criteria (Table 1), or using more elaborate screening instruments such as the Clinician Administered PTSD Scale (CAPS) (Blake et al. 1995) or a self-rating scale such as the PTSD Checklist (Military or Civilian Version) (Weathers et al. 1993).

Treatment

Treatment of PTSD may include several disciplines and approaches and can vary depending on the severity and chronicity of trauma symptoms and the presence of comorbid disorders. Most often, a phase-oriented approach to

treatment is utilized which includes behavioral stabilization, psychoeducation, anxiety management, focused trauma work, relapse prevention, and aftercare (Herman 1992).

Once a diagnosis has been established, psychoeducation in group or individual formats detailing diagnosis and treatment is critical for both patient and family (American Psychiatric Association [APA] 2004; Foa et al. 2000; Turnbull and McFarland 1996; Van der Kolk et al. 1996). Educating patients about the phases of treatment reassures those frightened by the notion of psychiatric medication and psychotherapy, as well as sets appropriate expectations for treatment. The main goal of stabilization is to manage acute symptoms and improve current functioning with psychoeducation, medication, and anxiety management training. Once symptoms stabilize, patients are more able to engage in psychotherapy (Van der Kolk et al. 1996).

Psychotherapy

Psychotherapy aims to reduce symptom severity and improve global functioning and quality of life resulting in enhanced functioning in social and occupational areas. Psychotherapeutic interventions for PTSD with the strongest empirical evidence are those that include components of prolonged exposure (PE) and/or cognitive processing therapy (CPT) (APA 2004; Resick and Schnicke 1993; US Department of Veterans Affairs/Department of Defense 2010). In PE, the patient experiences the trauma imaginally or in vivo during planned treatment sessions, with a goal of diminishing distress by forming new associations. CPT focuses on the appraisal of the traumatic event and the emotions resulting from the event (i.e., cognitive distortions). Common cognitive distortions include perceiving the world as dangerous, seeing oneself as powerless or inadequate, or feeling guilty for outcomes believed preventable (Friedman 2006). In CPT, the patient engages in writing narratives of the trauma with a goal of processing the emotions and restructuring the dysfunctional beliefs.

Eye Movement Desensitization and Reprocessing (EMDR) has received some empirical support and is generally considered to be an evidence-based

treatment for PTSD (APA 2004; Friedman 2006). In EMDR, patients are instructed to imagine the painful traumatic memories and associated negative cognition such as guilt and shame while visually focusing on the rapid movement of the clinician's finger (Friedman 2006).

Acceptance and Commitment Therapy (ACT) is an emerging treatment for PTSD, having shown promising outcomes in a limited number of trauma research studies (Bean et al. 2017). The goal of ACT is to increase psychological flexibility while engaging in valued activities; ACT has been demonstrated to be effective in treating several other disorders, including substance abuse, depression, and chronic pain (Hayes et al. 2012). Given the often high rates of co-morbidity in PTSD and ACT's transdiagnostic application, it may prove to be an ideal treatment for PTSD.

Behavioral Activation (BA) is a behaviorally based treatment for depression that promotes engagement in behaviors that positively reinforce consequences, promoting behavioral momentum and a collateral improvement in mood (Martell et al. 2010). There have been some studies demonstrating effectiveness for BA in treating trauma: notably, BA has relatively low dropout rates (Jakupcak et al. 2006, 2010).

Regardless of the psychotherapeutic treatment modality, prior behavioral stabilization is critical as some comorbid conditions may preclude the introduction of treatment (e.g., suicidality, self-injurious behavior, or psychosis). Further, initiating "trauma-focused psychotherapy" prior to stabilization may exacerbate preexisting comorbid symptoms of depression and substance abuse. Promising work in these areas of comorbidity, such as Cognitive Behavior Therapy for Insomnia (CBT-I), has application in enhancing psychotherapy for PTSD (Schwartz and Carney 2012). Group-based psychotherapy is also commonly used, focusing on psychoeducation, anger, depression, substance use, social and vocational skills, relaxation training, as well as other facets of PTSD (APA 2004; Foy et al. 2000).

Pharmacological Management

Selective serotonin reuptake inhibitors (SSRIs) have the most empirical evidence for efficacy in the treatment of all four PTSD symptom clusters

and are usually considered as a first-line treatment for PTSD (APA 2004; National Institute for Clinical Excellence 2005; Schoenfeld et al. 2004). SSRIs are also effective agents for the treatment of comorbid mood and anxiety disorders commonly associated with PTSD. Both paroxetine and sertraline have received FDA approval for the treatment of PTSD in the United States (APA 2004). In Canada, only paroxetine has Health Canada approval for the treatment of PTSD.

Second-generation, dual-acting antidepressants such as venlafaxine and mirtazepine are widely used in treating major depression and other anxiety disorders but have less empirical data demonstrating their efficacy for the specific treatment of PTSD (Chung et al. 2004; Connor et al. 1999; Davidson et al. 2003; Hopwood et al. 2000; Smajkic et al. 2001). As such, they are often considered as a second-line treatment in patients who have failed to respond to a trial of an SSRI. However, since SSRIs have not demonstrated their efficacy in the treatment of Vietnam or combat-related PTSD thus far (Friedman et al. 2007; Schoenfeld et al. 2004), second-generation antidepressants may be considered as first-line treatment. Tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) have some limited data to support their use in the treatment of combat-related PTSD (Davidson et al. 1990; Kosten et al. 1991). However, they are not commonly used because of their side effect profile and potential for toxicity.

Benzodiazepines are not recommended as monotherapy for the treatment of PTSD (Friedman 2006) but are sometimes used as adjuncts in treating anxiety or insomnia (APA 2004). There is a risk of rebound insomnia when a benzodiazepine, used as a hypnotic, is discontinued especially after long-term use (Cooper et al. 2005). The revised Veterans Affairs/Department of Defense Clinical Practice Guidelines advise against the use of mood stabilizers such as topiramate, divalproex, and lamotrigine in the treatment of PTSD (US Department of Veterans Affairs/Department of Defense 2017). They also highlight that atypical antipsychotics are not recommended for the treatment of core PTSD symptoms; rather, they may be used for comorbid disorders.

³Faculty of Medicine, Nursing and Health Sciences, Monash University, Melbourne, VIC, Australia

Synonyms

Postural control assessment; Standing balance assessment

Definition

Posturography is the study of an individual's control of their upright body position and balance in standing. It typically includes the measurement of body alignment while standing quietly, or in response to visual, postural, or environmental perturbation, or while performing dynamic

tasks. Postural control in standing relies on the integration of multisensory information from the vestibular system, vision, and somatosensory information including cutaneous sensation (foot pressure against the floor) and proprioception (joint position sense). Posturography commonly includes conditions to test the function of these systems, such as closing the eyes, introducing conflicting visual information, or altering the angle of the support surface. This assesses the relative contribution and integration of these systems to regulate balance. The ability to maintain smooth control of an upright body position in standing is an essential part of everyday life and needed to successfully manage everyday tasks such as reaching into cupboards, bending down, or catching balls in standing.

Balance control in standing improves as developmental maturation occurs across early to middle childhood. Compared to age-matched peers, children with autism have been found to have reduced stability in standing, reflected by greater postural sway, especially in the sideways (mediolateral) direction. This has been shown in studies of children with low intelligence (Kohen-Raz et al. 1992) and normal intelligence (Chang et al. 2010; Minshew et al. 2004; Molloy et al. 2003). Postural deficits have been shown in both adults and children with autism, but the differences are larger in children (Minshew et al. 2004), suggesting that the development of the postural system in children with autism may be delayed (Fournier et al. 2010; Minshew et al. 2004). Children with autism may thus appear less stable or coordinated in standing activities than their age-matched peers.

These deficits in postural control may be due to difficulty in the integration of multiple sensory input or adaptation to altered sensory input. Individuals with autism have greater difficulty with standing with eyes closed (Gepner et al. 1995; Minshew et al. 2004; Molloy et al. 2003), or in conditions where the standing surface is angled (referenced to sway), or vision is altered (Minshew et al. 2004). This suggests that these children may have more difficulty with challenging balance activities in some outdoor situations where the ground may be soft or compliant, the level of light fluctuating, or when vision is

occupied by tracking the motion of balls or people. Children with impaired balance control in standing are likely to have comparable or greater difficulties with walking and running activities, where the demand for rapid and efficient sensory-motor integration is greater. There are currently no empirical studies which have investigated the functional significance of difficulties in standing balance; however, clinically, it is suspected that this may impact negatively on children's proficiency and ability in school and recreational physical activities such as sport.

Power of Attorney (Financial and Property Management)

Annemarie M. Kelly and Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

A Power of Attorney (POA) is a legal agreement that grants an agent the authority to act in the place

of a principal in matters of finances and property (American Law Institute 2006). Under a POA instrument, a principal authorizes an agent to perform a particular set of duties for the principal's benefit. A POA agent (historically referred to as an "attorney-in-fact") must act according to the terms and specifications set forth in the POA record (Garner 2019a).

A POA should be distinguished from a "Healthcare Power of Attorney," which is typically a separate and distinct legal instrument that grants an agent the specific authority to make decisions about the principal's healthcare and medical treatment (Nicolaidis et al. 2016).

Principles of a Power of Attorney

A POA can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their caregivers (Sharpe and Baker 2007). Establishing a POA can be beneficial in a variety of contexts, including: (1) personal convenience in managing financial and property affairs; (2) providing additional security in the event of an unexpected injury or other health condition; or (3) assisting a principal who has a progressively worsening health condition or legal incapacity (American Bar Association 2020). Unlike a legal guardianship or conservatorship, a POA appointment does not require a court order from a judge to be valid. Depending on a principal's individual circumstances, utilizing a POA agent may be preferable over a court-appointed conservator or guardian (Sitkoff and Dukeminier 2017). Because POAs do not require court orders for amendments, they can usually be swiftly revised or terminated at a principal's discretion.

Several nonprofit and for-profit organizations offer state-specific forms for POAs online; however, it is a best practice to consult with an attorney who is licensed in your state of residence when executing a POA (U.S. Government Services and Information 2020). As the National Council on Disability explains, "Although forms are often available online, powers of attorney are powerful documents that require careful consideration by the principal, who may benefit from a lawyer's advice and drafting experience, particularly in the area of

finances." (National Council on Disability 2018). Hiring an attorney to write your POA will ensure that your POA is valid in your home state and transferrable across state lines. It is strongly recommended to utilize an attorney to make certain that the terms of your POA for finances and property align with the specifications of your other legal documents and special needs planning instruments. The goals listed in your POA should coordinate with other long and short-term goals set forth in items such as your advanced medical directives, living will, special needs trust, and/or ABLE account (also referred to as a "529A account") (Ho and Lee 2019).

In some states, parents with children age 17 and younger may choose to enact a Minor POA document (also known as a "Child Power of Attorney"). This type of POA allows a parent to grant control over the decisions made for their child for a specified period of time, often between 6 and 12 months (e.g., Power of Attorney for Care of a Minor Child Act of 2003). A Minor POA may be used in situations where a parent is separated from and/or unable to assist the child because of employment-related travel, military service, incarceration, or a health condition.

Power of Attorney Authority and Timeframes

With a POA in place, an agent can take any action on behalf of a principal that is permitted by the POA agreement's language. The terms within a POA confirm both the scope of an agent's authority and the POA's timeframe. There are two primary types of POAs that differ according to the scope of the agent's authority: (1) General POA (granting extensive authority), and (2) Limited POA (also referred to as "Special Power of Attorney," granting specific authority) (American Jurisprudence 2020). See Table 1 "Agent Authority under a Power of Attorney." A General POA empowers an agent to make a broad range of business decisions – these may include signing checks to pay bills, managing all real estate property, and arranging financial affairs (*Zaubler v. Picone* 1984). Under a Limited POA agreement,

Power of Attorney (Financial and Property Management), Table 1 Scope of an agent’s authority under a power of attorney

Agent’s authority type	Agent’s scope of authority	Examples of tasks assigned to an agent
General power of attorney	An agent has powers apply to broad groups of issues.	1. Sign checks to pay all bills 2. Manage all real estate property 3. Manage the principal’s pension, retirement, annuity, or other income 4. Communicate all health care directives 5. Open a financial account 6. Conduct business operations
Limited power of attorney (also known as special authority)	An agent has specific powers that are limited to a certain act or type of act.	1. Complete a home closing sale 2. Purchase an automobile 3. Open a bank account 4. Refinance a mortgage or student loan 5. File last year’s tax return 6. Purchase a specific stock or bond

the agent’s authority is specifically stated and applies to a set number of activities (*In re Grubin 2012*). An agent with limited authority might perform the following duties: complete a home closing sale, purchase an automobile, open a bank account, arrange affairs to refinance a loan, or file the principal’s taxes (Requirements for filing power of attorney [2020](#)).

Unless a principal specifies that his or her POA should become effective upon a future date, event, or contingency, an agent’s authority under a POA is considered effective when the principal signs the POA document. There are four types of

Power of Attorney (Financial and Property Management), Table 2 Power of attorney timeframes

Length type	Definition
Permanent	Empowers the agent to act on the principal’s behalf throughout the principal’s lifetime and until the principal’s death.
Temporary	Empowers the agent to act on the principal’s behalf for limited time frame.
Springing	Empowers the agent to act on the principal’s behalf only in the event of a particular occurrence. This type of POA term can be designed as either permanent or temporary in scope. Without a triggering occasion, a springing power of attorney will never take effect.
Durable	Empowers the agent to act on the principal’s behalf after a principal becomes legally incapacitated. This type of POA term can be designed to be permanent, temporary, and/or springing in scope.

timeframes for a POA: permanent, temporary, springing, and durable (Andersen and Gary [2018](#)). See [Table 2](#) “Power of Attorney Timeframes.” A permanent term POA empowers the agent throughout the principal’s lifetime. A temporary term POA is written to last for a definite period of time; it can be written to take effect immediately or begin on a specified date. In contrast, a springing term POA will begin only upon the occurrence of particular future event. For example, a POA with springing terminology can be designed to take effect if a physician determines that the principal is unable to care for himself or herself because of an unforeseen accident or a decline in functional status. Lastly, a durable term POA empowers the agent to act on the principal’s behalf after a principal becomes “legally incapacitated” (Garner [2019b](#)). Depending on the principal’s preferences, a POA with a durable designation can be written as permanent, temporary, and/or springing in scope. In the majority of states, a POA is considered to be durable unless it explicitly provides that it is terminated by the legal incapacity of the principal. In a nondurable POA term, the agent’s authority will stop in the event the principal becomes legally incapacitated.

Creating a Power of Attorney

In the USA, POA agreements are largely governed by the probate laws of the individual states. The requirements for a valid POA can differ greatly among state laws. In most states, four primary elements are required to create a valid POA – the principal must: (1) be a legal adult, which is age 18 or older in most states; (2) have “legal capacity”; (3) sign the POA (or, in the event the principal is unable to make a signature, direct another individual to sign the principal’s name in the principal’s presence); and (4) ensure that at least one individual witnessed the signing of the POA, preferably a notary public (U.S. Consumer Financial Protection Bureau 2016). Though a notarization of the principal’s signature is not typically required to create a valid POA, it is a best practice to include a notary public’s authorization on all POAs to confirm the document authenticity. See Table 3 “Key Elements for a Power of Attorney.”

Ideally, a principal should appoint at least two individuals as agents and confirm the order of their authority. With a primary principal and a secondary individual in reserve, the latter will only receive authority under a POA in the event the primary principal is unavailable to serve the as the agent. It is also a best practice to provide copies of your POA document to friends, family members, or others who may have a need to know about its details. In some states, principals are required to file a record of their POA with the recorder’s office in their home county (also sometimes referred to as the “county clerk”).

Legal Capacity in Power of Attorney Matters

In the USA, the doctrine of “legal capacity” applies to the principal’s state of being when signing the POA agreement. For purposes of entering into a POA, a principal’s legal capacity is defined as the ability to understand the fundamental benefits, risks, and effect of entering into the agreement (Parker 2016). Historically, the term legal capacity was sometimes referred to as

Power of Attorney (Financial and Property Management), Table 3 Key Elements for a power of attorney

Element number	Element	Description
1	The principal must be a legal adult.	Age 18 is the legal threshold for adulthood in most states.
2	The principal does not have “legal capacity.”	Individuals lack legal capacity when they are unable to manage their property or business affairs because of the following: (1) they cannot receive and evaluate information; and/or (2) they cannot make or communicate decisions even with the use of technological assistance.
3	The principal must sign the POA agreement.	In the event the principal is unable to sign the POA agreement, another individual may sign on the principal’s behalf provided that the signer is acting on the principal’s direction and in the principal’s presence.
4	Other individuals witness the principal’s signature of the POA agreement	Witnesses serve to confirm and acknowledge the authenticity of the POA. As a best practice, a POA agreement’s signature should be certified by a notary public.

“legal competency.” Individuals do not have legal capacity when a judge rules that they are entirely incapable of managing financial or personal affairs. In these instances, the individual is unable to fully safeguard himself or herself against harm to self, wealth, and/or property. A judge will determine that a principal lacks legal capacity

based on evidence presented to the court, including medical records and testimony from treating physicians, mental health professionals, caregivers, family members, friends, and the individual under review for a legal capacity judgment (United States General Accounting Office 2004). As part of its guidance on best practices for state POA legislation and policy, the U.S. Uniform Law Commission offers the following clarification regarding legal capacity issues: “[I]n recognition that disability does not necessarily render an individual incapable of property and business management. . .definition of incapacity stresses the operative consequences of the individual’s impairment—inability to manage property and business affairs—rather than the impairment itself” (Uniform Law Commission 2006).

A principal’s legal capacity must be distinguished from his or her mental ability (Dudley and Edmonds 2018). Legal capacity embodies individual legal rights to have standing to bring and defend lawsuits and enter into/execute legally binding contracts. In contrast, mental or cognitive capacity issues in conservatorship matters focus on a person’s ability to express personal will and intentions (Kohn et al. 2013). Even in cases where the principal has been declared as lacking legal capacity, state laws usually require POA agents to take a principal’s preferences into account when making life-changing decisions about finances and property (National Council on Disability 2019).

Ending a Power of Attorney

There are six common reasons why a POA will end: (1) the principal passes away; (2) the principal chooses to revoke the POA; (3) the principal becomes legally incapacitated (and the POA is not designated as “durable” in length); (4) a court determines that the POA is invalid; (5) the agent can no longer carry out the required responsibilities; and (6) an agent has developed a conflict of interest that interferes with his or her obligations to the principal (U.S. Consumer Financial Protection Bureau 2015). See Table 4 “Common Reasons for Ending a Power of Attorney Agreement.”

Power of Attorney (Financial and Property Management), Table 4 Six common reasons for ending a power of attorney agreement

Reason number	Justification for invalidation, revocation, or termination
1	The principal passes away.
2	The principal chooses to revoke the POA agreement.
3	The principal becomes legally incapacitated and the POA agreement is explicitly designated as “nondurable.”
4	A court rules that the POA agreement is invalid due to fraud, the principal’s lack of legal capacity when entering into the agreement, or other fairness concerns.
5	The agent can no longer carry out the required responsibilities.
6	The agent has developed a conflict of interest that interferes with his or her obligations to the principal.

When POAs are challenged in court, they are often overturned based on the following considerations: a judge declares the POA as invalid based on evidence that the principal did not have legal capacity when entering into the POA; the agent has developed a conflict of interest against the principal; or some other fraud (also known as “misrepresentation”) occurred to induce the principal to enter into the POA.

In most jurisdictions, a principal can terminate a POA at any time and at his or her discretion. All types of POAs end after the principal passes away. A former POA agent can continue to act as the principal’s legal representative when he or she is also designated as the executor of the principal’s estate (Furrow et al. 2018). A POA agent will maintain the authority to pay the principal’s debts, manage estate affairs, and make funeral arrangements after the principal is deceased only when a principal appoints the same individual (or organization) as both POA agent and estate executor.

Power of Attorney for Healthcare (Durable Healthcare Power of Attorney and Medical Power of Attorney)

Annemarie M. Kelly and Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Defined

A power of attorney for healthcare (also referred to as a healthcare power of attorney and hereafter as “HCPOA”) is a legal advance directive that grants an agent the authority to make decisions about the principal’s healthcare and medical treatment. Under a HCPOA instrument, a principal

authorizes an agent to perform a particular set of duties for the principal's benefit. A HCPOA agent (historically referred to as an "attorney-in-fact") must act according to the terms and specifications set forth in the HCPOA record (Garner 2019a).

HCPOA documents that are labeled as "durable" do not end in the event the principal becomes legally incapacitated (U.S. Department of Health & Human Services National Institute on Aging 2016). Agents under HCPOA agreements are often referred to as "patient advocates" because they are charged with understanding and carrying out principals' care preferences (Sabatino 2010). A HCPOA can be designed to be permanent or limited based on the principal's needs. For example, a HCPOA can be designed to commence only in the event the principal is unconscious or otherwise unable to communicate healthcare directives (Marks et al. 2019).

A HCPOA should be distinguished from a power of attorney (POA) for estate planning, which is a legal agreement that grants an agent the authority to act in the place of a principal in matters of finances and property (American Law Institute 2006).

Common Abbreviations and Acronyms in Healthcare Power of Attorney Matters

HCPOAs have many possible synonyms and abbreviations including medical power of attorney (MPOA), power of attorney for healthcare (POA-HC, POAHC, or alternatively HPOA), and advanced directive (AD). Because the majority of HCPOA documents are written to be "durable" in nature, these instruments are also commonly referred to as a durable healthcare power of attorney (DPOA-HC or DPOAHC) or durable power of attorney for healthcare (DHCPOA). Traditionally, a HCPOA agent was referred to as an "attorney in fact." Today, an agent acting under a HCPOA is more commonly referred to as a patient advocate, healthcare agent (HCA), healthcare proxy (HCP), healthcare surrogate, or surrogate decision-maker (e.g., Meisel 2015).

Principles of a Healthcare Power of Attorney

A HCPOA can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their caregivers (Satkoske et al. 2020). Establishing a HCPOA can be beneficial in a variety of contexts, including (1) personal convenience in managing health and personal wellness affairs; (2) providing additional security in the event of an unexpected injury or other health condition; or (3) assisting a principal who has a progressively worsening health condition or legal incapacity (American Bar Association 2011). Unlike a legal guardianship or conservatorship, a HCPOA appointment does not require a court order from a judge to be valid. Depending on a principal's individual circumstances, utilizing a HCPOA patient advocate may be preferable over a court-appointed conservator or guardian (U.S. National Council on Disability 2018). In most cases, HCPOAs can be revised or terminated quickly and conveniently at a principal's discretion. As a best practice, a principal should confirm his or her revocation of a HCPOA in a signed, notarized document. In limited circumstances – often when the wording in a HCPOA is unclear and a principal is unable to communicate his or her intentions – a judge will review a HCPOA and amend it with a court order.

Several nonprofit and for-profit organizations offer state-specific forms for HCPOAs online (e.g., Regents of the University of Michigan 2017). State-specific HCPOA forms are often available at no cost to the public online through state governments, state bar associations, or state medical societies (e.g., State of Illinois Power of Attorney Act Illinois Statutory Short Form: Power of Attorney for Healthcare, 2020 and State of Iowa Durable Power of Attorney for Healthcare Form 2020). Free, standardized forms are often limited in nature and provide a range of check-off options to try to suit a principal's needs – these lists can sometimes fail to fully communicate a principal's unique preferences and needs. HCPOA forms for the general public range in quality and is typically less comprehensive than individualized documents prepared after a consultation with a private attorney who specializes in special needs planning.

It is a best practice to consult with an attorney who is licensed in your state of residence when executing a HCPOA (U.S. Government Services and Information 2020). Hiring an attorney to write your HCPOA or review an existing document will ensure that your HCPOA is valid in your home state and transferrable across state lines. It is strongly recommended to utilize an attorney to make certain that the terms of your HCPOA align with the specifications of your other legal documents and special needs planning instruments. The HCPOA patient advocate should take care to understand the principal's entire special needs plan. The goals listed in your HCPOA should coordinate with other long- and short-term goals and spending priorities set forth in items such as your power of attorney for finance and property, special needs trust, and/or ABLE account (also referred to as a "529A account") (Ho and Lee 2019).

A HCPOA's instructions should be updated regularly and include wording that is detailed and specific. There are two primary reasons why HCPOA forms are sometimes found to be impractical or unhelpful: (1) the HCPOA language intended to guide the patient advocate is outdated and no longer relevant to the principal's current situation; and (2) the principal's directions for his or her patient advocate are too vague and ambiguous (e.g., subject to multiple reasonable interpretations) to provide a patient advocate with meaningful guidance on making tough decisions (Graber 2017). All in all, the overarching goal of a HCPOA is to clarify a principal's values and treatment preferences so that the patient advocate can work to implement those plans in collaboration with healthcare providers (Zerbo et al. 2015). Principals and their caregivers should review their HCPOA yearly to revisit whether certain values and treatment goals have changed in relation to their health and level of functioning.

Healthcare Power of Attorney Authority and Timeframes

With a HCPOA in place, a patient advocate can take any action on behalf of a principal that is permitted by the HCPOA agreement's language

(Elster and Parsi 2020). Unless a document expressly states otherwise, a HCPOA covers any healthcare-related service or procedure. HCPOAs typically cover all decision-making to maintain, diagnose, treat, or otherwise affect an individual's physical or mental condition (e.g., U.S. Department of Health & Human Services National Institute on Aging 2016). In some states, the scope of a HCPOA can also include wellness and personal care services. The terms within a HCPOA will confirm both the scope of the patient advocate's authority and the HCPOA's timeframe. There are two primary types of HCPOAs that differ according to the scope of the patient advocate's authority: (1) general HCPOA (granting extensive authority) and (2) limited HCPOA (also referred to as "special power of attorney," granting specific authority) (American Bar Association 2011). See Table 1, Scope of a Patient Advocate's Authority under a Healthcare Power of Attorney.

Unless a principal clearly specifies that his or her HCPOA should become effective upon a future date, event, or contingency, a patient advocate's authority under a HCPOA is considered effective when the principal signs the HCPOA document. Most HCPOA documents are designed to be "durable" in nature, meaning they do not end in the event the principal becomes "legally incapacitated" (Garner 2019b). In most states, a HCPOA is automatically considered to be durable unless the document specifically states that the principal wants a nondurable HCPOA. Under a nondurable HCPOA, a patient advocate's authority will stop in the event the principal becomes legally incapacitated (Palmer and Harmell 2016). A person's legal capacity must always be distinguished from his or her ability to communicate desires and intentions (Mitchell 2015). Legal capacity can only be officially determined by a judge – it embodies an individual's legal rights to have standing to bring and defend lawsuits and enter into/execute legally binding contracts.

There are four types of timeframes for a HCPOA: permanent, temporary, springing, and durable (American Bar Association 2009). See Table 2, Healthcare Power of Attorney Timeframes. A permanent term HCPOA empowers the patient advocate throughout the

Power of Attorney for Healthcare (Durable Healthcare Power of Attorney and Medical Power of Attorney), Table 1 Scope of a Patient Advocate’s Authority under a Healthcare Power of Attorney

Patient advocate’s authority type	Patient advocate’s scope of authority	Examples of tasks assigned to a patient advocates
General power of attorney for healthcare	Patient advocate has powers apply to broad groups of issues	1. Make all healthcare-related decisions 2. Manage all medical appointments 3. Make arrangements for surgeries, procedures, and treatments 4. Communicate all healthcare directives
Limited power of attorney for healthcare (also known as special authority for healthcare)	Patient advocate has specific powers that are limited to a certain act or type of act	1. Make healthcare-related decisions for a specific surgery, procedure, or treatment 2. Manage medical appointments related to a mental health only 3. Make arrangements for only physical and occupational therapies 4. Communicate healthcare directives related to end-of-life matters only

principal’s lifetime. A temporary term HCPOA is written to last for a definite period of time; it can be written to take effect immediately or begin on a specified date. In contrast, a springing term HCPOA will begin only upon the occurrence of particular future event. For example, a HCPOA with springing terminology can be designed to

Power of Attorney for Healthcare (Durable Healthcare Power of Attorney and Medical Power of Attorney), Table 2 Healthcare Power of Attorney Timeframes

Length type	Definition
Permanent	Empowers the patient advocate to act on the principal’s behalf throughout the principal’s lifetime and until the principal’s death.
Temporary	Empowers the patient advocate to act on the principal’s behalf for limited timeframe.
Springing	Empowers the patient advocate to act on the principal’s behalf only in the event of a particular occurrence. This type of HCPOA term can be designed as either permanent or temporary in scope. Without a triggering occasion, a springing HCPOA will never take effect.
Durable	Empowers the patient advocate to act on the principal’s behalf after a principal becomes legally incapacitated. This type of HCPOA term can be designed to be permanent, temporary, and/or springing in scope.

take effect if a physician determines that the principal is unable to care for himself or herself because of an unforeseen accident or a decline in functional status.

Creating and Ending a Healthcare Power of Attorney

In the USA, HCPOA agreements are largely governed by the contract laws of the individual states. The requirements for a valid HCPOA can differ greatly among state laws (e.g., Uniform Law Commission 1993, 2014). In most state jurisdictions, four primary elements are required to create a valid HCPOA – the principal must (1) be a legal adult, which is age 18 or older in most states; (2) have legal capacity; (3) sign the HCPOA (or in the event the principal is unable to make a signature, direct another individual to sign the principal’s name in the principal’s presence); and (4) ensure that at least one individual witnessed the signing of the HCPOA, preferably a notary public (American Bar Association

(2018); see also Moyer et al. 2013). Though a notarization of the principal’s signature is not typically required to create a valid HCPOA, it is a best practice to include a notary public’s authorization on all HCPOAs to confirm the document

Power of Attorney for Healthcare (Durable Healthcare Power of Attorney and Medical Power of Attorney), Table 3 Key Elements for Creating a Healthcare Power of Attorney

Element number	Element	Description
1	The principal must be a legal adult to appoint a patient advocate.	Age 18 is the legal threshold for adulthood in most states.
2	The principal must have legal capacity to agree to the terms of the HCPOA.	Individuals lack legal capacity when they are unable to manage their property or business affairs because of the following: (1) they cannot receive and evaluate information; and/or (2) they cannot make or communicate decisions even with the use of technological assistance.
3	The principal must sign the HCPOA agreement.	In the event the principal is unable to sign the HCPOA agreement, another individual may sign on the principal’s behalf provided that the signer is acting on the principal’s direction and in the principal’s presence.
4	Other individuals witness the principal’s signature of the HCPOA agreement.	Witnesses serve to confirm and acknowledge the authenticity of the HCPOA. As a best practice, a HCPOA agreement’s signature should be certified by a notary public.

authenticity. See Table 3, Key Elements for Creating a Healthcare Power of Attorney.

Ideally, a principal should appoint at least two individuals as patient advocates and confirm the order of their authority. With a primary principal and a secondary advocate in reserve, the latter will only receive authority under a HCPOA in the event the primary principal is unavailable to serve as the patient advocate. It is also a best practice to provide copies of your HCPOA document to your primary physician, treating physicians, friends, family members, or others who need to know its details (Nicolaidis et al. 2016).

In some cases, a principal’s healthcare provider, family member, or another individual will challenge the validity of a HCPOA in court. A judge may decide to order that a HCPOA is invalid based for one of the following reasons: (1) the judge determines that sufficient evidence exists to prove that the principal did not have legal capacity when entering into the agreement; (2) the patient advocate has developed a conflict of interest against the principal; (3) the patient advocate can no longer carry out the responsibilities required under the HCPOA; or (4) or some other fraud (also known as “misrepresentation”) occurred to induce the principal to enter into the HCPOA (Sitkoff and Dukeminier 2017).

As a general rule, a principal can terminate a HCPOA at any time and at his or her discretion. In some states, a HCPOA will remain effective following death of the principal so that the patient advocate can process organ donations, autopsy matters, and burial or cremation services (e.g., General Statutes of North Carolina 32A-19(b), 2020). Apart from these end-of-life matters, a HCPOA ends after the principal passes away.

Practice Guidelines in Autism

Iain McClure
The Royal Hospital for Sick Children,
Edinburgh, UK
University of Edinburgh, Edinburgh,
Scotland, UK

Definition

Practice guidelines have two basic purposes. First, to promote effective care by reinforcing good practice. Second, by promoting change in professional practice where this does not comply with current best practice. In autism spectrum disorder (ASD), a significant number of practice guidelines have now been developed. This section focuses specifically on clinical guidelines, used in

healthcare, but also applicable in educational and other relevant settings.

Even as recently as 10 years ago, clinicians working in ASD assessment and intervention had little in the way of a “road map” advising them which approaches had a reliable and valid evidence base and which did not. The situation was even more confusing for people with ASD and their carers. Rapid developments over the last 10 years in ASD practice guideline development have reduced much of that uncertainty, but, as a corollary, successive guidelines have revealed the extensive gaps in the ASD evidence base and the research that is now required.

Clinical practice guidelines are developed by multiprofessional groups that are locality (region or state) or nationally representative. A systematic review is undertaken to identify and critically appraise the scientific literature. Guideline recommendations are then explicitly linked to (and graded according to the strength of) the supporting evidence. The guideline development group (GDG) needs to be representative of the key constituencies within the field under study. This is paramount in a politically sensitive field such as ASD. The ASD GDG should aim to represent all facets of the ASD multiagency, parent/carers, and voluntary network within the geographic area that the guideline pertains to. In order to build this consensual and representative approach, GDG composition needs to be carefully constructed.

First, a chairman is recruited to lead the development of the practice guideline. Second, the guideline chair has to then recruit the GDG. The chair and GDG then have to clarify the guideline’s exact remit, a clue which is often to be found in the guideline title. For example, the guideline *Assessment, diagnosis and clinical interventions for children and young people with autism spectrum disorders* published by the Scottish Intercollegiate Guidelines Network (SIGN) in 2007 (SIGN 98 2007) explains the basic remit and range of its approach. Its emphasis on “clinical” interventions implies that it does not aim to cover primarily educational-based interventions, for example (although in ASD, it is hard to apply exact cutoff points in regard to types of interventions).

The GDG then needs to decide on key themes within the agreed remit. From these themes, “key questions” are generated. These questions aim to clarify and identify the field of evidence that needs to be sought. For example, in SIGN 98, key question 12 asked: “*Which conditions occur in association/comorbidly with ASD, and can their presence be specifically excluded or confirmed?*” (SIGN 98 2007). This question was then used to generate search terms in the literature search for that area of enquiry (i.e., comorbidity in ASD).

The process of evidence gathering and its subsequent analysis is varied, according to different guidelines. The highest standards of scientific validity and reliability tend to be found in those guidelines produced by national guideline organizations, such as the Scottish Intercollegiate Guidelines Network (SIGN) or the National Institute for Clinical Excellence (NICE) for England and Wales. Other guidelines may have somewhat more relaxed processes of evidence gathering and data analysis, especially relevant for a field such

as ASD where there is comparatively little quantitative “high-level” evidence, but where it is felt important to make recommendations across all aspects of the care agenda, in order to influence uni- or multiprofessional practice. This explains why, for example, that in regard to the recommendation levels in SIGN 98 (SIGN 98 2007) and the *New Zealand guideline on ASD* published in 2008 (Ministries of Health and Education 2008), there is a significant disparity of levels of evidence recommendation, despite the fact that the two guidelines conducted their international literature searches at approximately the same time. The SIGN guideline makes far less recommendations at the higher levels (i.e., A or B) than its New Zealand counterpart, due to its tighter evidence gathering, analysis, and rating criteria. Also the grades of recommendation systems are different, so that in SIGN 98 a level D recommendation denotes nonanalytic studies, for example, case reports, case series, or expert opinion, while in the NZG, expert opinion qualifies as a level C recommendation.

Practice Guidelines in Autism, Table 1 SIGN’s evidence rating process. (Copyright SIGN, reproduced by permission)

SIGN’s evidence gathering and analysis process are explained in Table 1.

This includes systematic reviews and meta-analyses, randomized controlled trials (RCTs), cohort and case control studies, nonexperimental studies and expert opinion. Second, the evidence gathered is rated according to its quality. Third, the evidence is summarized in evidence tables. Fourth, the guideline development group considers this evidence and rates it into considered judgment forms. Fifth, these forms then generate graded, evidence-based recommendations.

Table 2 shows the SIGN system of rating evidence levels, using a numerical scoring system and asterisks. Thus, an evidence level of 1⁺⁺ denotes high-quality meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias. At the other end of the evidence-rating spectrum, an evidence level of 4 denotes expert opinion (i.e., evidence that has not even been scrutinized within a nonanalytic study).

Table 3 shows how grades of recommendation are stratified in the SIGN system. The highest level of evidence-based recommendation (level A) denotes an evidence level that includes at

least one meta-analysis, systematic review, or RCT rates as 1⁺⁺ and that is directly applicable to the target population of the evidence-based guideline. Alternatively, this grade of recommendation can be achieved by the existence of a systematic review of RCTs or a body of evidence consisting principally of studies rated as 1⁺ that is directly applicable to the target population and that demonstrates overall consistency of results. At the other end of the spectrum of graded recommendations, level D denotes that the evidence level available is rated as 3 or 4, or that it is evidence extrapolated from studies rated as 2⁺⁺. An important point to remember about the resulting recommendation gradings is that, as the New Zealand ASD guideline states, “the attached grading reflects the rigour of the studies providing the evidence rather than an indication of the importance of the recommendation” (Ministries of Health and Education 2008).

Practice Guidelines in Autism, Table 2 SIGN’s levels of evidence. (Copyright SIGN, reproduced by permission)

SIGN levels of evidence	
1 ⁺⁺	High-quality meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias
1 ⁺	Well conducted meta-analyses, systematic reviews of RCTs, or RCTs with a low risk of bias
1 ⁻	Meta-analyses, systematic reviews of RCTs, or RCTs with a high risk of bias
2 ⁺⁺	High-quality systematic reviews of case-control or cohort studies
	High-quality case-control or cohort studies with a very low risk of confounding, bias, or chance and a high probability that the relationship is causal
2 ⁺	Well conducted case-control or cohort studies with a low risk of confounding, bias, or chance and a moderate probability that the relationship is causal
2 ⁻	Case-control or cohort studies with a high risk of confounding, bias, or chance and a significant risk that the relationship is not causal
3	Nonanalytic studies, e.g., case reports, case series
4	Expert opinion

Practice Guidelines in Autism, Table 3 SIGN grades of recommendation. (Copyright, SIGN, reproduced by permission)

SIGN grades of recommendation	
A	At least one meta-analysis, systematic review, or RCT rated as 1 ⁺⁺ , and directly applicable to the target population
	<i>or</i>
	A systematic review of RCTs or a body of evidence consisting principally of studies rated as 1 ⁺ , directly applicable to the target population, and demonstrating overall consistency of results
B	A body of evidence including studies rated as 2 ⁺⁺ , directly applicable to the target population, and demonstrating overall consistency of results
	<i>or</i>
	Extrapolated evidence from studies rated as 1 ⁺⁺ or 1 ⁺
C	A body of evidence including studies rated as 2 ⁺ , directly applicable to the target population and demonstrating overall consistency of results
	<i>or</i>
	Extrapolated evidence from studies rated as 2 ⁺⁺
D	Evidence level 3 or 4
	<i>or</i>
	Extrapolated evidence from studies rated as 2 ⁺

Historical Background

Practice guidelines in ASD are a fairly recent phenomenon. The main initial guideline development activity took place in the USA toward the end of the 1990s and early 2000s. These were either unidisciplinary national guidelines (Filipek et al. 2000; Volkmar et al. 1999) or multi-professional but state based (New York state Department of Health, Early Intervention program 2000; California Department of Developmental Services 2002). Thereafter, guideline development activity spread to Europe (Le Couteur 2003; SIGN 98 2007) and New Zealand (Ministries of Health and Education 2008). The difference with these later guidelines was that they were both national and multi-professional. Subsequent guideline development has been more targeted, using the work completed by previous GDGs which are relevant to universal geographical localities but focusing on specific aspects that are geographically particular. For example, in 2009, the National Institute for Clinical Excellence (NICE) for England and Wales decided to limit the remit of its forthcoming ASD guideline for children and young people to clinical assessment only. NICE decided not to undertake a more extensive evidence review to look at clinical interventions and treatments, because that work had been only recently done by SIGN, NICE's sister organization in Scotland. Therefore, subsequent national guideline approaches seem to be becoming more targeted, reflecting previous work undertaken and, perhaps, a more cost-conscious financial climate.

All of the published guidelines, whether by unidisciplinary, state, or national organizations, contain unique and interesting approaches which means that all of them repay close examination. For example, the New York State guideline (New York state Department of Health, Early Intervention program 2000) restricted its remit to 0–3 years and in this regard may be seen as one of the most detailed surveys of this crucial epoch regarding ASD. Information for “clinical clues” that should point the clinician to signs of possible autism in a child of this age range were carefully evidence based. For this reason, SIGN 98 (SIGN

98 2007) deliberately adopted this aspect of the New York guideline for its own recommendation, as being the best evidence base available. This is an example of a practice guideline becoming the source of the available evidence base for subsequent guidelines.

The *National Autism Plan for Children* for England and Wales (Le Couteur 2003) is unique in that it not only considered the evidence base for its various recommendations, but it also developed a consensus set of recommendations as regards what an ASD clinical service for pre-school and primary-school-aged children should consist of in terms of basic requirements. These suggestions are not, strictly speaking, evidence based, because they were the product of clinical consensus (i.e., they constitute level 4 evidence). However, given that no subsequent guideline group has developed as detailed a description of the different tiers of an ASD service, the NAPC recommendations have gained increasing importance over the years as a point of reference and, effectively, as evidence.

SIGN 98 produced perhaps the most robust and extensive survey of the international evidence regarding ASD up to its publication date. In addition, it was the first guideline to raise the important issue of validity and reliability of ASD diagnosis as regards subject recruitment for scientific studies. Simply put, SIGN's GDG asked, can researchers provide a reliable and valid guarantee that the subjects entered into their research studies, whom they claim have ASD, actually *do have* the condition (as defined by categorical classification systems)? The GDG argued that if researchers cannot do this, their research findings, no matter how “groundbreaking,” must be accordingly downgraded. To back up this approach, SIGN 98's GDG developed a sliding scale of reliability and validity for diagnosis as regards study subject recruitment (SIGN 98 2007) (see Table 4).

Cultural factors are a key parameter to consider in a condition such as ASD. The NZG (Ministries of Health and Education 2008) has provided a fascinating lead in this regard, with its sensitive consideration of the particular needs and interests of New Zealand's Maori community. Presumably any subsequent national multiprofessional

Practice Guidelines in Autism, Table 4 Criteria for assessing the reporting of the diagnosis of ASD in the literature. (Reproduced by permission of SIGN)

A. Components of diagnostic assessment		
1. A recognized process of obtaining information in necessary domains, usually by multidisciplinary or multiagency personnel		
2. Mapping of the resulting information into a recognized classification system such as DSM-IV or ICD-10 (see Sect. 2.2)		
3. Assessment using a recognized and published diagnostic instrument		
B. Components of a reliable diagnosis		
Increasing accuracy and reliability		Use of a process and diagnostic classification system, and an instrument (i.e., 1, 2, and 3, from A)
		1. Use of a process and a diagnostic classification system
		or
		2. Use of an instrument and a diagnostic classification system
		The use of a process, a diagnostic classification system, or an instrument, used singly
		Diagnosis simply stated

NB each component of the assessment should be explicitly stated in the study/report under consideration

guideline will need to seriously consider following this benchmark in its design, if cultural diversity is an issue pertaining to that population.

Current Knowledge

The most recent clinical practice guidelines have been those developed by the Scottish Intercollegiate Guidelines Network on *ASD in children and young people* published in June 2007 (SIGN 98 2007), which covers the epoch from 0 to 19 years and the New Zealand guideline on *Autism Spectrum Disorder*, published in March 2008, which considers ASD in the whole age range, including adults (Ministries of Health and Education 2008). This section will therefore consider the evidence base according to these two

guidelines. It is important to note, however, that these two guidelines “stand on the shoulders” of previous guidelines. For example, in the NZG, its section on diagnosis and assessment of young children is based on the *National Autism Plan for Children* (Le Couteur 2003) and “further reference was made” to the *Autistic Spectrum Disorders Best Practice Guidelines for Screening, Diagnosis and Assessment* that was developed by the California Department of Developmental Services (California Department of Developmental Services 2002).

As explained earlier, SIGN 98 and the NZG demonstrate different levels of evidence recommendation, with SIGN using tighter criteria, being less able to make recommendations generally or certainly higher-level (A or B) recommendations. In addition, the scope of the NZG is wider than SIGN 98, in that it covers the whole age range as opposed 0–19 years inclusive, and it considers educational interventions, for example, whereas SIGN 98 focuses on clinical interventions (or educational interventions that have a clinical application). If SIGN had considered the more general spread of educational interventions, it is unlikely that much of the evidence gathered would have been suitable for evidence-based recommendation, within SIGN’s evidence-rating system. This is an example of guidelines being pitched at the level for which they are required, either by a professional group or by a national government, to determine health and education policy. Theoretically, SIGN’s tighter criteria mean that its recommendations are more applicable internationally, which explains why they have been adopted in countries other than Scotland. A downside of this tighter approach, however, may be that important clinical areas (especially to patients and carers), for example, sensorimotor development, are left undirected in regard to the (lower) levels of evidence that are available. Sometimes, such gaps can be filled by the GDG stating “good practice points” (GPPs), and these can be found in both SIGN 98 and the NZG but, again, at possibly different criteria levels.

This section follows the structure of SIGN 98’s presentation of the evidence, with

slight modifications and therefore specifically limits its remit to “assessment, diagnosis and clinical interventions.” Readers who wish to consider the broader evidence base for educational interventions, for example, should look at the NZG.

Definitions and Concepts

SIGN 98 uses the term “autism spectrum disorders” (ASD) to cover the ICD-10 conditions termed autism, atypical autism, and Asperger’s syndrome (World Health Organization [WHO] 1993), and the NZG uses the term “ASD” to cover the DSM-IV-TR conditions of autistic disorder, Asperger’s disorder, and PDD-NOS (American Psychiatric Association 1994). Both guidelines consider both classification systems. SIGN 98 defers to ICD-10 in any difference of terminology between it and DSM-IV-TR. The NZ guideline follows DSM-IV-TR.

Recognition, Assessment, and Diagnosis

Recognition in Primary Care

Screening Both guidelines state that population screening for ASD is “not recommended” (SIGN at level C and the NZG at level B).

Surveillance SIGN 98 explains that, “as part of the core programme of child health surveillance,” clinicians can help to identify early those children who may have ASD or other developmental disorders. At level D recommendation, SIGN 98 states:

clinical assessment should incorporate a high level of vigilance for features suggestive of ASD, in the domains of social interaction and play, speech and language development and behaviour and that:

CHAT or M-CHAT can be used in young children to identify clinical features indicative of an increased risk of ASD, but should not be used to rule out ASD.

While the NZG does not make such specific recommendations, it recommends, at level C, that “health and education professionals should take regular opportunities (at least at 8–12 months, 2–3

years and 4–5 years) to discuss the child’s development with parents.”

SIGN 98 provides three useful tables which consider “warning signs” suggestive of possible ASD in the three age ranges of preschool and

Practice Guidelines in Autism, Table 5 Additional warnings of possible ASD in adolescents. (Copyright, SIGN. Reproduced by permission)

Warning signs
<i>General picture</i>
– Long-standing difficulties in social behaviors, communication, and coping with change, which are more obvious at times of transition (e.g., change of school, leaving school)
– Significant discrepancy between academic ability and “social” intelligence, most difficulties in unstructured social situations, e.g., in school or work breaks
– Socially “naïve,” lack common sense, not as independent as peers
<i>Language, nonverbal skills, and social communication</i>
– Problems with communication, even if wide vocabulary and normal use of grammar. May be unduly quiet, may talk at others rather than hold a to-and-fro conversation, or may provide excessive information on topics of own interest
– Unable to adapt style of communication to social situations, e.g., may sound like “a little professor” (overly formal), or be inappropriately familiar
– May have speech peculiarities including “flat,” unmodulated speech, repetitiveness, use of stereotyped phrases
– May take things literally and fail to understand sarcasm or metaphor
– Unusual use and timing of nonverbal interaction (e.g., eye contact, gesture, and facial expression)
<i>Social problems</i>
– Difficulty making and maintaining peer friendships, though may find it easier with adults or younger children
– Can appear unaware or uninterested in peer group “norms,” may alienate by behaviors which transgress “unwritten rules”
– May lack awareness of personal space or be intolerant of intrusions on own space
<i>Rigidity in thinking and behavior</i>
– Preference for highly specific, narrow interests or hobbies, or may enjoy collecting, numbering, or listing
– Strong preferences for familiar routines, may have repetitive behaviors or intrusive rituals
– Problems using imagination, e.g., in writing, future planning
– May have unusual reactions to sensory stimuli, e.g., sounds, tastes, smell, touch, hot or cold

school-age children and in adolescents. The pre-school table comes from the New York guideline (New York state Department of Health, Early Intervention program 2000) and the school-age table is from the NAPC (Le Couteur 2003). The NZG also uses the NAPC concepts in its similar tables. Table 5 from SIGN 98 was developed as expert consensus by the SIGN 98 guideline development group.

Screening of High-Risk Groups In addition, SIGN 98 considers screening of high-risk groups (so-called secondary screening) and recommends, at level C, that “the use of an appropriate structured instrument may be a useful supplement to the clinical process to identify children and young people at high risk of ASD.”

Timing of Diagnosis SIGN 98 also considers the evidence for the timing of diagnosis, explaining that “the evidence regarding the minimum age at which ASD can be reliably diagnosed is not clear.” It makes the level D recommendation that “ASD should be part of the differential diagnosis for very young (pre-school) children displaying absence of normal developmental features, as typical ASD behaviours may not be obvious in this age group.”

Methods of Assessment

Initial Assessment Both SIGN 98 and the NZG recognize that initial assessment will, in the NZG’s words, “be undertaken by an individual practitioner” (level B recommendation). SIGN 98 explains that “those (multiprofessional colleagues) involved in carrying out the initial assessment should be aware of the core features of ASD as well as of the wide range of different possible presentations.” Both guidelines advise that “if on the basis of initial assessment, it is suspected that a child or young person may have ASD, they should be referred for specialist assessment.”

Specialist Assessment SIGN 98 explains that, because a diagnosis of ASD may be seen as “a lifelong ‘label’,” “it is of equal importance that clinicians diagnose, and not diagnose, accurately.”

Therefore, both guidelines advise that specialist assessment should be undertaken by “a multi-disciplinary team of health care practitioners experienced in ASD” (level B recommendation). The multiprofessional approach is recommended because “it may identify different aspects of ASD and aid accurate diagnosis” and collaborative multiprofessional conclusions will enable informed intervention with “effective educational, behavioural, physical, emotional, social and communication strategies. . .to promote development.”

NZG also recommends that “diagnostic assessment of young people and adults should be comprehensive” and “involve the person concerned in interview and observation” and that “formal pathways for diagnostic assessment of young people and adults should be developed” (level C recommendation).

Components of Specialist Assessment

(a) History taking (parent/carer interview)

SIGN 98 explains that taking an “ASD-specific diagnostic history” is an important component of an ASD assessment because “without it, evidence of ASD-like behaviour cannot be put into context” (level D recommendation). Although ASD-specific history-taking instruments can be “useful” “as a means of improving the reliability of ASD diagnosis” (level C recommendation), SIGN 98 explains the paramount importance of clinicians keeping “a global perspective” of the patient’s circumstances in mind, “taking into consideration the possibility of comorbidities and the possible differential diagnoses.” In addition, the NZG advises that “if the person taking the developmental history is not medically trained, then the medical history and examination should be completed separately.”

(b) Clinical observation/assessment (child/young person assessment/interview)

SIGN 98 recommends that “healthcare professionals should directly observe and assess the child or young person’s social and communication skills and behaviour” (level D recommendation). Again, there is a recommendation that clinicians “should consider using ASD-specific observational instruments,

as a means of improving the reliability of ASD diagnosis” (level C recommendation). Such aids would include instruments like ADOS-G (Lord et al. 2000).

(c) Contextual and functional information

The NZG explains that “direct observation of the child’s behaviour in an unstructured setting is essential” and SIGN 98 states the good practice point that “information about children’s functioning outside the clinic setting, should be routinely obtained from as many sources as is feasible.”

Individual Profiling

Because people with ASD vary considerably as regards their individual difficulties and strengths, SIGN 98 recommends that “all children and young people with ASD should have a comprehensive evaluation of their speech and language and communication skills, which should inform intervention” (level D recommendation).

The NZG recommends in addition that “the assessment of intellectual, adaptive and cognitive skills” associated with ASD “should be seriously considered and, where possible and appropriate, formally assessed” (level B recommendation).

Biomedical Investigations

SIGN 98 makes a level D recommendation that “where clinically relevant” all children and young people with ASD should have their physical status examined “with particular attention to neurological and dysmorphic features”; undergo karyotyping, fragile X DNA analysis, and audiological examination; and be investigated to rule out recognized etiologies of ASD (such as tuberous sclerosis). In addition, SIGN 98 explains its awareness of the “considerable interest in the role of the immune system and the influence of bowel function” in ASD and that it conducted “an extensive search” for research into this area. SIGN 98 explains that its GDG “found no research evidence of an acceptable level in support of the clinical use” of investigations aimed at supporting such biomedical theories and that, therefore, in respect of this controversial area, it is “not possible at present to make a recommendation.”

Conditions Associated with ASD

SIGN 98 makes a level C recommendation that clinicians should “be aware of the need to routinely check for comorbid problems in children and young people with ASD” and that “where necessary, detailed assessment should be carried out to accurately identify and manage comorbid problems.”

The NZG makes three recommendations covering this area that “differential diagnosis must be covered during diagnostic assessment” and “must be thorough and cover all conditions commonly confused with ASD and those known to coexist with ASD” (level C). Thirdly, the NZG recommends that clinicians “must have a good understanding of the different forms of expression of ASD symptomatology across developmental stages and the symptomatology of common coexisting and alternative conditions” (level B).

Nonpharmacological Interventions

Communication Interventions

Support for Early Communication Skills SIGN 98 recommends that “interventions to support communication in ASD are indicated, such as the use of visual augmentation, e.g. in the form of pictures of objects” (level D).

Interventions for Social Communication and Interaction

SIGN 98 recommends that “interventions to support social communication should be considered for children and young people with ASD, with the most appropriate intervention being assessed on an individual basis” (level D).

Behavioral/Psychological Interventions

SIGN 98 explains that these types of interventions fall into three groups: intensive behavioral programs “aimed at improving overall functioning and altering outcome”; interventions which “aim to address specific behavioural difficulties associated with ASD,” for example, sleep disturbance; and interventions which do not fall into either of the first two categories.

Intensive Behavioral Programs SIGN 98 explains that “most intensive behavioural programmes for ASD are based on the principles of behaviour modification using applied behavioural analysis (ABA).” While the NZG does not comment on specific interventions in this category, SIGN 98 recommends that “the best known of the intensive ABA interventions,” the Lovaas program, “should not be presented as an intervention that will lead to normal functioning” (level A).

Interventions for Specific Behaviors The NZG recommends that “behaviour management techniques should be used to intervene with problem behaviours” (level A). SIGN 98 recommends that behavioral interventions “should be considered to address a wide range of specific behaviours. . . both to reduce symptom frequency and severity and to increase the development of adaptive skills” (level B).

Auditory Integration Training SIGN 98 recommends that “auditory integration training is not recommended” (level A).

Facilitated Communication SIGN 98 recommends that “facilitated communication should not be used as a means to communicate with children and young people with ASD” (level A).

Biomedical and Nutritional Interventions

Recognizing that this is an area of importance and focus for many parents and carers of people with ASD, SIGN 98 looked for evidence justifying or ruling out any such interventions, for example, exclusion diets. However, SIGN 98 states that there was “insufficient evidence” to meet “the criteria set for the review and therefore no recommendation can be made.”

Pharmacological Interventions

Risperidone

SIGN 98 recommends that risperidone is “useful for short term treatment of significant aggression, tantrums or self injury in children with autism”

(level B); however, it does not define “short term.” The NZG issues similar level B recommendation about risperidone, advising that “monitoring for side effects should be carried out on a regular basis.”

Methylphenidate

SIGN 98 recommends, at level B, that methylphenidate “may be considered for treatment of attention difficulties/hyperactivity in children or young people with ASD.” The NZG recommends, at level C, that methylphenidate “is effective for some children with ASD and co-morbid ADHD” but “should be used with caution because of the high risk of adverse effects.”

Fluoxetine

The NZG recommends, at level B, that SSRIs in general, including fluoxetine, “may be effective for some children with ASD and high anxiety and/or obsessive symptoms” but that, however, “in the absence of good evidence, these drugs should be used with caution and careful monitoring.”

Secretin

SIGN 98 recommends, at level A, that “secretin is not recommended for use in children and young people with ASD.”

Melatonin

At level B, the NZG recommends that melatonin “may be useful for improving sleep in children with ASD who have impaired sleep,” and at level D, SIGN 98 recommends that melatonin “may be considered for treatment of sleep problems which have persisted despite behavioural intervention.”

Other Treatments

The NZG recommends, at level B, that “typical” antipsychotics, such as haloperidol, “are effective in reducing motor stereotypies, temper tantrums and improving social relatedness,” but “these drugs have a high rate of adverse effects and are not recommended for first-line use.”

Service Provision

Training and Support for Parents

Information Provision SIGN 98 recommends that “professionals should offer parents good quality written information and an opportunity to ask questions when disclosing information about their child with ASD.” This information should be provided “in an accessible and absorbable form” (level D). The NZG issues similar guidance.

Meeting Support Needs SIGN 98 recommends that “education and skills interventions for parents of pre-school children with ASD should be offered” (level B).

Information for Discussion with Children, Young People, Parents, and Carers

Providing information and support

At the Time of Diagnosis

The NZG makes recommendations for this area, nearly all at level C, including that “formulation is the necessary next step from assessment” and that “clarity of diagnosis should be the goal of assessment and formulation.” The NZG also recommends that all diagnostic assessments “should include a detailed written report” that “disclosure of diagnosis of older teens and adults. . . should take into consideration the wishes of the person concerned” and that “sources of post-diagnosis support should be identified.” Finally, the NZG recommends that “information on ASD and support services should be available at all diagnostic disclosure interviews” (level B). SIGN 98 provides similar advice but at good practice point level only.

Recommendations for Research

SIGN 98 explains that further research is required “to address numerous areas where there is insufficient evidence to make a recommendation or to support existing clinical practice.” The guideline identifies several examples within each of four key areas:

- Recognition, assessment, and diagnosis
- Nonpharmacological interventions

- Pharmacological interventions
- Service provision

Future Directions

Given the cost of practice guideline development, it may be that the era of large, national, multi-professional guidelines such as those conducted by SIGN and in New Zealand (and the two guidelines soon to be published by NICE as regards both children and young people and adults in 2011–2012) is coming to an end. Instead, subsequent national guideline groups have elected to substantially follow the evidence-searching strategy of previous guidelines in order to save time and cost and to survey evidence from the dates of previous completed surveys (as is currently the case in Italy, which is using SIGN 98 in this way).

Thus, guideline organizations can assist each other, the international autism community, their carers, and clinicians to cultivate the evaluation of the evidence base as an ever-expanding tapestry of activity. Guideline development, in this way, provides fascinating and exciting opportunities for international collaboration. The information that will accrue from such collaboration may even generate its own contribution to the evidence base.

Furthermore, guideline organizations have been developing new ideas to spread the information available to the widest possible readership. For example, in 2009, the UK Academy of Medical Royal Colleges commissioned SIGN and the Royal College of Physicians and Surgeons of Glasgow (RCPSG) to publish two pilots of extant SIGN guidelines on the World Wide Web as resources for continuing professional development. The SIGN guideline on ASD was chosen as one of these initiatives and will be the first to be published (SIGN website; <http://www.sign.ac.uk> in 2012). This e-CPD module contains the SIGN 98 guideline itself and also contains embedded “think points” that help the reader develop their understanding of the information provided. Having read through this embellished version of the guideline, any clinician, from anywhere in the

world, can then complete the multiple choice questions that examine the clinician's understanding of the guideline.

Thus, evidence-based guidelines on ASD are now more widely available to the professional and lay public than ever. This hopefully will combat the bewildering effect of information overload that confronts the parent who, on receiving a diagnosis of ASD for their child, types “*autism*,” “*ASD*,” or “*autism treatments*” into a web search engine. There is no possible way that even the best informed lay person could reliably navigate the millions of hits that inevitably will result. For this reason alone, guideline organizations need to keep up with the possibilities inherent in information technology, to ensure that people with ASD, their carers, and the professionals who try to help them are provided with the most valid and reliable evidence base to date, in an accessible and understandable format.

[Pragmatic language disorder](#); [Social \(pragmatic\) communication disorder](#); [Social communication disorder](#)

Short Description or Definition

Pragmatic language impairment (PLI) is a type of developmental language impairment in which there is disproportionate difficulty with pragmatics and social communication compared to the structural aspects of language such as grammar and vocabulary.

Categorization

PLI is not included as a category in DSM-V. PLI is a descriptive term that is used to identify the type of language problem present. PLI is still in clinical use but has been replaced in the research literature

and autism diagnostic practice by the term “Social Communication Disorder” or “Social (Pragmatic) Communication Disorder” (SPCD), principally by consensus (Swineford et al. 2014). DSM-V presented SCD as a new and distinct category from autism spectrum disorder (ASD) and specific language impairment (SLI). SCD is described as: a condition evident from early childhood, in which there is a persistent impairment in using language for social interactions (pragmatics). The impairment is accompanied by limitations in functional social participation that are not explained by low cognitive functioning or ASD. Nonverbal communication is also affected.

Epidemiology

There are no prevalence figures for PLI since it is not recognized as a category in diagnostic models. Precise estimates of prevalence of SCD are difficult to determine due to difficulties associated with differential diagnosis. Using DSM-V criteria for SCD in a Korean community sample of 7–12-year-old children, Kim et al. (2014) estimated the prevalence of SCD to be a 0.49%, commenting that this may be conservative. Ketelaars et al. (2009) found the prevalence of pragmatic language impairments to be 7.5% of children in a large community sample in the Netherlands, though it is not clear that these children would meet DSM-V criteria for SCD. Gender differences were found in this study; more boys were affected than girls in a ratio of 2.6:1. Botting and Conti-Ramsden (1999) identified 22% of elementary school-age children attending specialist language units in the UK as having PLI, indicating that amongst this severely affected group, a diagnosis of PLI or SCD is not uncommon.

Natural History, Prognostic Factors, Outcomes

Children with PLI/SCD show late emergence of language, including receptive language delay and an early history of autistic features (such as echolalia) with impaired social relationships (Adams

2015). By 5–6 years of age, there are relatively few problems with grammar and phonology and more fluent language has emerged, often with persistence of significant receptive language problems. A full profile of PLI/SCD emerges at this stage as the contrast between structural language and pragmatic competence becomes more marked.

Time spent in special educational provision by children with PLI/SCD is longer than that of children with other types of language impairment. Pragmatic difficulties in the primary school years may be related to emotional and behavior difficulties (Van Agt et al. 2011; Helland et al. 2014). Adults with a PLI history have relatively normal literacy and structural language skills, fewer autism symptoms than comparable ASD

individuals, and better work skills outcomes than adults with a history of SLI (Whitehouse et al. 2009).

Clinical Expression of Illness

(i) *Pragmatic behaviors in naturalistic social interactions:* Table 1 sets out pragmatic language behaviors observed in children who have PLI, typically after 4–5 years of age. These are present in conversational interactions or other unstructured talk. This account of pragmatic errors is based on the Gricean view of pragmatics as cooperative behavior between speakers. That is, talk should be relevant and informative.

Pragmatic Language Impairment, Table 1 Main pragmatic features observed pragmatic language impairment

Verbosity	The child talks at length about a topic and offers more than would be expected in cooperative talk
Loquacity	The child talks at length within one conversational turn; the impression is of a monologue rather than a genuine conversational exchange
Domination of interaction	The overall impression is that the child is dominating the interaction by being verbose/loquacious and not allowing the other speaker a turn
Initiations	The child initiates exchanges of information (a) more frequently than expected, by making many unsolicited statements or by asking many questions; or (b) the child is relatively passive or appears uninterested by making no or very few initiations
Responsiveness	The child does not respond to a conversational overture such as a question or a clear cue from the other speaker that it is his turn to talk; appears to ignore the other speaker
Turn-taking	There are problems with taking turns in interactions so that speakers talk at the same time. Signals (intonation, grammatical, and nonverbal signs) that are given by one speaker to another to indicate that the turn to talk is being passed over are not detected by the child or he is verbose and presses on with his talk over the other speaker.
Information management	The child offers too much information in the interaction and thus appears pedantic or odd. The same child may offer too little information, so that intended meaning is vague and the listener has difficulty following meaning
Reference	The child does not specify clearly objects, actions, or people who are being talked about; he does not take into account how much the listener knows already or could be expected to work out from the linguistic or physical context
Topic	The child changes topic suddenly (topic shift) or provides an unexpected link to a topic unrelated to the current exchange (topic drifting or linking). Shifting/drifting can occur to topics which are not relevant to the situation or may represent attempts to return to recurrent topics/favored interests
Coherence	The child's talk is disorganized, with unclear references and confused sequences in narratives, leading to loss of overall meaning of the discourse
Cohesion	The child does not use correct linguistic markers (e.g., pronouns) to indicate links between different utterances or turns resulting in confusion for the listener
Speech acts	Most children with PLI of school age show a normal range of speech act forms (e.g., questions, statements, denials) but may not always use these in optimal contexts

Pragmatic Language Impairment, Table 2 High-level language and comprehension deficits in PLI

Nonliteral interpretations	The child misinterprets, or interprets literally, nonliteral language such as metaphors, idioms, jokes, sarcasm
Inferential comprehension	Inference refers to the ability to retrieve unstated information from discourse and is fundamental to above-sentence level comprehension. The child with PLI typically shows limited ability to make appropriate inferences, particularly in naturalistic discourse, and may therefore misinterpret meanings
Comprehension of discourse	The child is unable to follow complex verbal interactions and may therefore not be able to contribute meaningful responses. Most children with PLI have some deficits in inference comprehension and in applying world knowledge to discourse comprehension
Misinterpretation of meanings in context	Words which have multiple meanings (e.g., bank, glasses) are misinterpreted by the child because he does not use the context (usually the sentence, but sometimes a physical context) to identify the correct meaning
Narrative organization	The child shows disorganized narratives (stories, accounts of recent events), leaving listeners confused as to actually happened. Many behaviors contribute to poor narrative organization such as inadequate reference, poor coherence, and cohesion as well as features of language impairment (e.g., poor vocabulary)

(ii) *High-level language difficulties* refer to the level of language processing at above-sentence level, for example, conversational discourse, understanding stories, narrated events, printed text in books. These are apparent on formal tasks and standardized testing but also pervade the child’s everyday functioning. Table 2 lists the main high-level language deficits seen in PLI and describes how these affect communication.

Semantic errors and immaturities do occur in children with PLI and are similar in nature and proportion to semantic behaviors seen in SLI. Use of semantically related substitutions or replacement of advanced vocabulary by earlier acquired words is common in all language impairments. Word-finding deficits may be present in PLI but are not universal in this group and are more common in SLI. Children with PLI may present with one or many other language deficits such as lag in sentence comprehension or expressive vocabulary (see evaluation below).

(iii) *Other communication features* of some children with PLI are similar to the social communication deficits in children with high-functioning ASD (HFASD). These are

(a) stereotyped language: the child inserts

“learned” sentences or phrases (e.g., “all of a sudden”) into interactive contexts where they have no meaning; (b) unusual or stereotyped intonation; (c) abnormalities of non-verbal communication: limited use of gesture to supplement communication, gaze aversion; and (d) associated characteristics such as social cognition deficits, difficulty with peer relations, behavioral difficulties, anxiety, and depression have been reported.

Heterogeneity in PLI

Children with PLI rarely demonstrate all of behaviors listed above. Some children may show mild pragmatic impairments and social interaction problems with relatively good language skills; others show multiple pragmatic, language, and social characteristics, frequently, and in all types of interactions.

Evaluation and Differential Diagnosis

Evaluation of the communication features of pragmatic language impairments in children follows three main principles:

- A comprehensive assessment must include assessment of language skills, pragmatic ability and social interaction.

- Since presentation of PLI is variable, evaluation should be individualized in order to pursue in-depth characteristics which should be targeted in intervention.
- Ideally evaluation should be carried out as part of a multidisciplinary assessment to address ASD and language characteristics.

Language, pragmatics, and social communication assessments should be carried out by a speech-language practitioner with experience in language disorders and autism. A combination of observational and formal assessment techniques will be used. The context of assessment is crucial. Functional deficits of social communication apparent in the child's everyday life may not be easy to observe in structured elicitation procedures or tests, even those dedicated to pragmatics, so test scores alone may overestimate ability. Evaluation should include interviews with carers and teachers.

Pragmatic skills shown in Table 1 are typically evaluated using observational checklists and naturalistic sampling such as classroom or family interactions or simple conversation in clinic. Before 4–5 years of age it may be difficult to identify problematic pragmatic behaviors, although some observational instruments of high quality are available (e.g., the Language Use Inventory (O'Neill 2007)).

There are no detailed normative data for the emergence of complex pragmatic behaviors in late pre-school to school-age children. All aspects of language skills including word and sentence level, in addition to the higher-level language skills shown in Table 2, need to be assessed by a specialist speech-language practitioner. Some standardized tests also have some pragmatic content, for example, Expression, Reception and Recall of Narrative Test (Bishop 2004), Test of Pragmatic Language-2 (Phelps-Terasaki and Phelps-Gunn 2007), and the Social Use of Language Test (Bowers et al. 2008).

An indication of the presence of PLI/SCD in children can be obtained using the Children's Communication Checklist (CCC-2) (Bishop 2003), a parent or teacher report instrument. Two summary CCC-2 scores can be derived: a General

Communication Composite which indicates the presence of communication impairment and a Social Interaction Deviance Composite which can indicate the presence of a disproportionate pragmatic impairment.

At the present time, differential diagnosis from other conditions is largely by consensus and convention rather than precise published criteria (Simms and Jin 2015). Differential diagnostic criteria are set out below alongside discussion of problematic areas.

Intellectual impairment is excluded as an explanatory factor in PLI using nonverbal IQ cut-off. PLI have nonverbal IQ >70; intellectual impairment nonverbal IQ <70. This is identical to the IQ cut-off used for SLI diagnosis, though narrower definitions of SLI use >85 cut-off. In clinical practice, children with PLI with nonverbal IQ in the range 70–85 are likely to present with a similar profile of language impairment as children with PLI who have nonverbal IQ >85.

PLI is differentiated from SLI by consideration of disproportionality of the impairment of pragmatics compared to the impairment in structural aspects of language such as grammar, vocabulary, and phonology. The Social Interaction Deviance Composite (SIDC) score of the CCC-2 can indicate the likely presence of PLI, but should not be used in isolation, as there is no precise cut-off between SLI and PLI. Caution is required, since SLI-type deficits (both expressive and receptive) may be perceived by CCC-2 respondents as affecting pragmatic competence. Significant receptive language difficulties, in particular, can result in the child adopting compensatory strategies in verbal interactions that appear bizarre and mimic some of the characteristics of PLI. Best diagnostic practice is to combine use of the CCC-2/SIDC with language assessment findings and specialist speech-language practitioner opinion.

It has been proposed that children with PLI/SCD can be differentiated in diagnosis from those with ASD (Bishop and Norbury 2002; Leyfer et al. 2008) since the former group demonstrate fewer repetitive behaviors and restricted interests dimension of ASD (Gibson et al. 2013). Reisinger et al. (2011) found relatively mild

autism characteristics (including restricted and repetitive behaviors) in a group of children with PLI compared to ASD children. However, Mandy et al. (2017) did not find evidence for SCD as a distinct category from ASD in a large sample of children and young people from a social communication disorders clinic. Bishop proposed that PLI might represent an intermediate state on a continuum between SLI and HFA, since children with PLI tended to move in and out of ASD diagnosis over time.

There remains a lack of confirmation of the differential status of ASD and SCD (Mazefsky et al. 2013; Foley-Nicpon et al. 2017). Additional instruments that focus on social communication and pragmatic deficits are still required 20 years after the first use of the term PLI. Contemporary research consensus is that PLI/SPCD is a condition on the borderlands of autism. The label of PLI or SCD may be useful where there is no diagnosis of autism provided but pragmatic problems requiring intervention persist. One difficulty of subsuming PLI/SCD under autism services is that children who require specialist language interventions may be assigned to generic autism behavioral programs and the effects of these are unknown with this population (Norbury 2014).

Treatments

Treatment for PLI is via a holistic, multi-disciplinary approach, taking into account priorities of children, carers, and other service users. Communication treatments for PLI are directed toward the language, pragmatic, and social interactional elements of the condition. Treatments can be direct (therapeutic activities and practice with a speech-language practitioner) and indirect (advice and training offered to teaching staff and parents). Ideally a combination of approaches should be instigated but specialist knowledge and expertise is essential. Children may also require other treatments for associated conditions at the same time as communication therapy.

Pre-school speech-language treatments are likely to be aimed at encouraging use of language

and establishing skills which underpin language comprehension, supplemented by advice on language facilitation to carers. Recognition is now given to the importance of early intervention for social use of language by increasing appropriate communicative intents and working in small groups (Parsons et al. 2017). These treatments should be delivered or supervised closely by speech-language practitioners.

Direct treatments for language impairment as the child enters the school years are diverse and will be matched to the individual child's profile. Language therapy techniques are used to target needs such as receptive language or word-finding difficulties. A substantial body of work on social communication interventions for children with language impairments is available (Brinton and Fujiki 1995; Timler et al. 2005). Pragmatic skills deficits are approached directly using metapragmatic therapy in which the child is encouraged to apply pragmatic rules in social interactions via self-monitoring. Social communication deficits are often treated in groups using a social skills approach, but this can lack individualization or targeting of specific skills. An integrated model of direct intervention, in which language, pragmatic and social communication therapies are matched to the individual needs of the child, is described in Adams and Gaile (2015). An expert summary of social language intervention principles and methods is provided by Fujiki and Brinton (2017).

Indirect support can be provided for classroom/home generalization of language goals and social communication via training of education support workers, teachers, and parents. Speech-language practitioners can provide advice on the level and complexity of language input and strategies for problem-solving difficult communication situations. Children may also require a number of personalized support strategies such as visual timetables.

Great care should be taken to distinguish between treatments that have a broad social communication function approach and those that focus on specific aspects of language pragmatics. There is a wide range of possible treatment approaches for broad social communication

needs; these are listed on the American Speech and Hearing Association website <https://www.asha.org>. However, not all of these treatments focus on language and pragmatics. The evidence for treatments of language pragmatic impair-

ments is relatively sparse (Gerber et al. 2012) compared to the vast literature on social skills interventions (Reichow and Volkmar 2010). Case reports of conversation treatments for children with SLI and/or PLI have demonstrated positive effects of intervention on pragmatic function and indicate appropriate methods of treatment (Brinton et al. 2004; Timler et al. 2005). Adams et al. (2012) showed some positive outcomes for individualized pragmatics and language intervention using the Social Communication Intervention Programme (SCIP). There is still a need for better evidence to support clinical practice in pragmatics intervention and a need for better outcome measures to support that research.

PLSI

Description

The *Pragmatic Language Skills Inventory* (PLSI; Gilliam and Miller 2006) is a 45-item, standardized, norm-referenced, teacher-rating instrument designed to assess the pragmatic language abilities of children ages 5 through 12 years. It is based on long-standing theories of pragmatic language defined as use of language in context.

As an objective measurement scale, it allows educators to document progress and can also assist in targeting instruction and intervention goals for IEPs and Section 504 Plans. The PLSI can be used by teachers, speech-language pathologists, and early interventionists for further data collection and research.

Children are rated on the PLSI by a teacher or other professional (rater) who is familiar with his or her pragmatic skills compared to others of the same age and gender. The rater should, therefore, be familiar with the child's skill sets in different

school settings and as well as the abilities of average children of the same age and gender. The rater uses a 9-point scale to assess the child against three areas: personal interaction (initiating conversation, asking for help, participating in verbal games, and using appropriate nonverbal communicative gestures), social interaction (knowing when to talk and when to listen, understanding classroom rules, taking turns in conversations, and predicting consequences for one's behavior), and classroom interaction (using figurative language, maintaining a topic during conversation, explaining how things work, writing a good story, and using slang appropriately). Each of these areas represents a PLSI subscale. Each subscale consists of 15 items for a total of 45 items which can be completed in approximately 10 min.

PLSI scoring and interpretation is done by an examiner. This person may be a speech clinician, teacher, or education professional knowledgeable in assessment and basic psychometrics. Raw scores for each subscale can be converted to percentile ranks and standard scores using reference tables. The standards scores for each of the three subscales can also be summed to determine the child's pragmatic language index. The PLI is a standardized score ($M = 100$, $SD = 15$) and represents overall performance.

Historical Background

The PLSI is based on theories of pragmatic language by Bates (1976) and Snow (1994), which specify language in social context as a system of rules ensuring social appropriateness and the clarity of the speaker or author's intent. Snow specifies pragmatic language as a system of conversational rules. These rules include participating in conversation turn taking; telling the truth; offering new, relevant, and appropriate amounts of information to the listener; requesting appropriate information; providing the correct amount of background information in context; using unambiguous as well as figurative speech; as well as changing language appropriately to each social situation (Bates 1976). Gilliam and Miller developed the PLSI to assess school-age children in the above areas.

Psychometric Data

The PLSI was standardized on 1,175 school-age children, representative of population in regard to race, gender, rural or urban residence, ethnicity, family income, parent education, and disability.

The reliability of the PLSI was estimated using coefficient alpha (content sampling), test-retest (time sampling), and interrater reliability (correlation between raters). Coefficient alphas were calculated for each of the subscales by gender and disability status. All coefficient alphas for the PLSI's subscales exceed .95. Test-retest reliability was estimated to range between .78 and .91. Interrater reliability was estimated to range between .85 and .90.

The criterion-prediction validity of the PLSI was estimated by examining the relationship between the PLSI and the *Test of Pragmatic Language* (TOPL; Phelps-Terasaki and Phelps-Gunn 1992). Correlation coefficients ranged between .50 (large) and .86 (very large). Exploratory factor analysis indicated the items loaded as expected on both a single factor and on the three PLSI subscales. Correlation coefficients between the PLSI subscales and the total index score ranged from .75 to .86. Finally, the PLSI diagnostic subgroups were rated by teacher in expected ways. Individuals with intellectual disabilities exhibited the lowest scores and individuals identified as gifted and talented exhibited the highest scores.

The PLSI allows children's pragmatic language skills to be evaluated using norm-referenced scores. Scores can be used to determine if the child exhibits characteristics of a pragmatic language disorder and should be referred for a more comprehensive language assessment. Guidelines are provided to assist the examiner in interpreting the results. The PLSI can be used to identify children with pragmatic language disorders, document progress in ability, collect data for research, and target pragmatic language goals.

Clinical Uses

The PLSI is intended to be used in diagnosis of a pragmatic language disorder in conjunction with other assessment results, observations, case

histories, and parent interviews. It provides reliable and valid scores in order to differentiate children who have little likelihood of having a disorder.

The PLSI's objective scale of measurement allows educators to document a child's progress in pragmatic language ability. Administration is quick and simple enough to facilitate frequent use. The test can be used for special education and regular annual evaluations and in conjunction with other data in order to make transition and extended-year decisions.

The PLSI can help teachers and other professionals evaluate children's pragmatic language skills and assist in setting pragmatic language goals. Items from the PLSI can be utilized as specific targets in goal planning and intervention in Individualized Education Plans (IEPs) and Section 504 Plans.

[PRS-SA \(Pragmatic rating scale-school age\)](#)

Description

The Pragmatic Rating Scale-School Age (PRS-SA) is a assessment tool designed for documenting social communicative behaviors that violate pragmatic rules. It is designed for use with individuals aged 4 years through adulthood whose cognitive and linguistic functioning ranges from mild impairment through the gifted level. The definition of "pragmatics" used here is the set of rules governing the social use of language.

Pragmatics

Communication is a vital component of human interaction. It is one of the primary means of keeping people connected to each other. Communication may happen for a wide variety of purposes, such as informing someone (e.g., that you will be late), requesting permission, making a promise, teasing, showing something of interest, asking for information, greeting, negotiating, and so forth. To ensure that communication between people is coherent and socially appropriate, every culture has unwritten (tacit) rules for how communication is to transpire. The tacit rules that guide conversation, or social discourse, are known as the rules of pragmatic language behavior. Grice (1975) defined a set of maxims that, when adhered to, result in coherent conversation. These maxims are basic principles that enable conversational partners to organize and construct their communication behavior in ways that are interpretable and socially acceptable to each other, including such things as not saying more than is necessary, making sure that what you say is relevant (and that you indicate how and why it is relevant). When these maxims are systematically violated, people are signaling something to their conversational partner that serves to ensure the coherence of the communication. For example, when violating the maxim that requires speakers to say what they believe to be true, a speaker will signal through the tone of their voice or through facial expressions or gestures that their statement is not meant to be taken seriously (e.g., when we

exaggerate to make a point or to convey sarcasm). At times, violation of the Gricean maxims or pragmatic rules is permissible. For example, we may allow someone who is upset to monopolize a conversation, knowing that this is an extenuating circumstance. If, however, a particular person consistently monopolizes conversations, or if a person fails to systematically signal, in socially appropriate ways, their intentional violation of pragmatic rules, communication breakdown, and/or barriers to successful social interaction will arise. Such behavior may be indicative of a pragmatic language impairment.

Pragmatic Rating Scale-School Age

There are six scales within the PRS-SA: (1) Speech Acts; (2) Presupposition/Theory of Mind; (3) Discourse Management; (4) Speech and language behaviors; (5) Suprasegmental Speech Characteristics; and (6) Nonverbal Communicative Behaviors that affect Pragmatics. Within each of these scales, there are a number of items that provide a discrete set of communicative behaviors to be rated by the clinician. Ratings involve scores that range from 0 (unaffected; no evidence for pragmatic error involving this specific behavior or set of behaviors) to 2 (clear violation of pragmatic rules associated with the behavioral feature(s) being coded for this item). Within the Speech Acts scale, a checklist is provided on which clinicians record occurrences of the client's or patient's production of specific types of speech acts (communicative intents) and whether these were expressed in pragmatically appropriate or inappropriate ways. At the end of the PRS, two additional ratings are made that permit the clinician to provide an overall clinical judgment of the client's or patient's pragmatic behavior. The scores generated from the PRS include the summary scores for each scale, an overall composite score representing a sum of all the scale scores, and the clinical impression scores.

Scoring of the PRS-SA is based on a conversational sample that is designed to elicit a natural communicative exchange. Specific probes are

embedded into the conversation that provides opportunities to observe the full range of pragmatic behaviors rated within the PRS-SA. It may be used with already established behavior sampling procedures that include conversation segments between the clinician and child, such as the Autism Diagnostic Observation Scale – Generic, Modules 2 through 4 (Lord et al. 2001). It may also be used to rate pragmatic behavior over a number of interactive events so that clinicians may observe variability in pragmatic behavior linked to different types of contexts that involve a variety of social demands and supports, conversational partners, and social rules (e.g., playing games vs joint project development with peers; conversations with authority figures; conversations at lunchtime).

Historical Background

Pragmatic language disorders are not identifiable through existing cognitive assessment tools, nor through standard measures of grammatical and semantic language functioning. To assess pragmatic skill, an instrument is needed that enables clinicians and researchers to document pragmatic behavior in contexts that mimic true communicative exchanges. Pragmatic behavior, by definition, is dependent on context. In fact, it is the very ability to flexibly adapt one's communicative behavior to the context at hand, in socially appropriate ways, that defines healthy pragmatic functioning.

The PRS was originally developed in the early 1990s to document social discourse variations in a family study of autism. Soon after the PRS was developed, it began to be utilized to study pragmatic behavior in individuals with autism and to examine social discourse impairment as an endophenotype in other genetic disorders, including obsessive compulsive disorder. Next, the PRS was revised for use with school-aged children. In 2010, the PRS-School-Age version began to be used in a multi-site social skills intervention study focusing on elementary school-aged children with autism spectrum disorder (ASD). It is now being used to study the broader autism phenotype in

school-aged siblings of children with autism. Norms are also being established for children aged 4 through 12 years.

The PRS was developed because there was no other assessment instrument available for identifying individuals with social discourse difficulties. Many individuals with pragmatic impairments are viewed as socially odd and experience considerable social rejection, but because standard assessment tools do not assess pragmatic language functioning, these individuals often remain unidentified and, thus, untreated. The PRS was designed to facilitate identification of individuals with pragmatic impairment, providing a systematic method for defining the nature of their social communication difficulties and an objective basis for justifying intervention when needed. The PRS enables clinicians and researchers to document social discourse (pragmatic) variations or impairment, which is important for many types of endeavors such as identifying endophenotypes in genetic studies, identifying individuals with pragmatic disorders who are in need of intervention (or who may meet inclusion criteria for an intervention study), and educating family members, teachers, and employers about the nature of pragmatic difficulties that an individual is experiencing. Identifying and treating pragmatic impairment is important because such impairment may threaten success at the workplace, the ability to form and sustain friendships, the ability to gain access to social networks, and so forth.

Psychometric Data

At the time of preparation of this document (2011), the only psychometric data available on the PRS involves data presented in scientific manuscripts. Those data may be used to obtain general thresholds for PRS scores that fall in the “typical” range, though those studies focus primarily on adults and high-functioning individuals with autism spectrum disorders (including non-ASD controls). However, psychometric data are presently being compiled on children between the ages of 4 and 12 years. Thus, in the near future,

there will be empirical data on school-aged individuals with typical development, non-ASD delays, and ASD.

Clinical Uses

The PRS has a variety of clinical uses.

1. *Documenting the presence of a pragmatic language delay or impairment.* Elevated scores on the PRS, in combination with a speech-language pathologist’s clinical judgment of pragmatic language impairment, are likely to be indicative of impaired pragmatic ability and the need for intervention services. The PRS provides clinicians with a structured system for documenting communicative behaviors that may be contributing to breakdowns in social engagement and social communication. The operationally defined behaviors that are scored within the PRS provide clinicians with a systematic means of observing communicative behavior. The PRS items focus the clinician’s attention on dimensions of communication that otherwise may be missed or attributed to a different type of impairment. Documenting the types of communication behaviors that are problematic (based on the PRS items receiving a score of “1” or “2”), and the degree to which communicative behavior is disrupted for each PRS item, enables clinicians to glean information about whether a pragmatic impairment exists, and if so, how extensive and severe the impairment may be. The organization of communicative behaviors into different categories within the PRS (see “[Description](#)”) further enables clinicians to determine whether a child’s social communicative difficulties are primarily related to non-social processes (e.g., grammar, articulation), or are directly linked to difficulty with social inferencing, ability to link his/her ideas to the ideas of others through the use of linguistic devices, and so forth. Thus, the PRS is useful in clinical decision-making regarding need for intervention services and determination of intervention goals.

2. *Identifying specific behaviors that contribute to the pragmatic difficulties that an individual is displaying.* As indicated above, the specific types of items to be scored within the PRS permit documentation of the communicative behaviors that vary from the norm. For each PRS item, clinicians select a score ranging from 0 (within normal limits) to 2 (sign of abnormality). Clinicians may examine the items for which individuals received scores of 1 or 2, and look for patterns of communicative behavior that are problematic for their client or patient. By identifying specific aspects of pragmatic functioning that are difficult for an individual, clinicians may begin to define intervention goals and conversational supports, with the aim of improving the pragmatic language skills of the individual. Using the PRS, clinicians are able to objectively document specific pragmatic behaviors that are problematic as they help children or adults to develop greater levels of self-awareness and insight about their own communicative behavior. This is likely to enhance therapeutic response as individuals with pragmatic language difficulties often require explicit explanation of pragmatic rules, which are implicitly learned by most individuals. The operationally defined PRS items and objectively defined scoring system enable clinicians to discuss children's communication behavior with parents, helping them to develop a clearer understanding of their child's difficulties and how to develop strategies for helping their child achieve greater levels of success in communication.
3. *Documenting treatment response and progress.* The capacity of the PRS to document improvement in response to intervention has not been established, but is in the process of being evaluated through an intervention study. A short form of the PRS has been developed for use within treatment sessions to rate children's pragmatic behavior. This short PRS form is being studied to determine its utility for providing feedback to children on their advances in pragmatic behavior during and across intervention sessions, and for record-keeping purposes (e.g., progress notes).
4. *Communicating with teachers and family members about the client's needs.* As indicated above, the PRS provides a clear and objective means of describing the pragmatic behaviors and skills of an individual when providing test results to teachers and family members. This helps them to focus on specific behaviors rather than on a global impression of a socially challenged individual, thereby fostering the use of targeted skill-enhancing strategies.

structure or form (phonology, morphology, syntax); content or meaning (semantics); and use of language in context (pragmatics; Bates 1976; Bloom and Lahey 1978). Difficulty with any of these language components – either singly or in combination – may result in a language disorder. Difficulty with pragmatics is one of the core features of autism spectrum disorder (American Speech-Language-Hearing Association [ASHA] n.d.).

Pragmatics is one aspect of a broader category known as *social communication* (Turkstra et al. 2016). Social communication is supported by an array of skills important to effective communication: social cognition (e.g., taking the perspective of another person, making inferences, understanding facial expressions); sociolinguistics (e.g., cultural influences, gender differences in communication, influences of different languages for multilingual speakers); and social interactions and relationships with peers (Adams 2005; Timler 2008; Timler et al. 2005). Pragmatics involves three main communication tasks: (a) using language for multiple purposes, (b) adapting language for different settings and communication partners, and (c) engaging in conversation and narrative discourse (Roth and Spekman 1984).

Pragmatics

Diane R. Paul
Clinical Issues in Speech-Language Pathology,
American Speech-Language-Hearing
Association, Rockville, MD, USA

Synonyms

Language use; Pragmatic communication; Pragmatic language; Social cognition; Social communication; Social thinking; Use of language; Use of language in context

Definition

Effective communication requires mastery and integration of multiple components of language:

Use of Language for Different Purposes

Language is used for different reasons (e.g., greet, comment, ask, promise). By speaking certain utterances, certain actions are accomplished. Therefore, these purposes of speaking are known as *speech acts* (Austin 1962; Searle 1969).

Individuals with autism may use language in a more limited way. For example, they may not greet people, comment, or ask questions.

Adapting Language to Setting and Communication Partner

A pragmatic language disorder may be apparent when individuals do not use language appropriate to the setting or the communication partner. They may use the same language in all places and with all people. They may use a loud voice in a movie theater or restaurant. They may be impolite to their boss or abrupt with a grocery clerk.

Conversation and Narrative Discourse

Conversations require speakers to take turns; to appropriately initiate, maintain, and change conversational topics; to know when to interrupt; and to modify utterances following a misunderstanding. Nonverbal behaviors are also an integral part of conversations, such as using gestures and facial expressions and knowing how close to stand when speaking to another person. Speakers follow a set of conversational rules related to the quantity, quality, relevance, and manner in which they speak (Grice 1975).

Following conversation rules involves social cognition, which includes perspective-taking. The ability to take the perspective of another person is known as *theory of mind*. Speakers need to be aware of what their listener already knows. They need to know how much background information to provide.

Conversation problems, which may result from autism, may include difficulty following the rules for conversation-interrupting, not answering a question, bringing up topics unrelated to what is being discussed, or talking about only one subject. Speakers with autism also may experience problems in perspective-taking (ASHA n.d.). They may talk about people their communication partner does not know or omit important details.

Conversational use and narrative discourse vary across cultures. Therefore, it is critical to know the appropriate cultural expectations before determining that a particular pattern of conversation or storytelling is a pragmatic disorder.

Narrative discourse involves telling stories and talking about personal events. Speakers need to tell stories in a certain order and describe events in sequence.

Narrative discourse problems, which may result from autism, may involve telling a story out of sequence or omitting important parts.

Speech-language pathologists assess and treat pragmatic language disorders that may affect academics, self-esteem, behavior, and relationships.

Pragmatic language intervention is designed to capitalize on strengths and address weaknesses that affect language use and facilitate the individual's social activities and participation by assisting

the person to acquire new communication strategies (verbal and nonverbal). Intervention is expected to result in improved social functioning and participation (ASHA 2004).

Praise

Rebecca Munday
The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Praise is the act of delivering positive statements by individuals in regard to a person, object, action, or idea. Praise can be delivered publicly so others have the ability to see or hear it or in private. Praise is often awarded after the completion of a task or an accomplishment. Praise can be delivered verbally, gesturally, and visually. Some examples of praise are saying "Good job" or "Way to go" and "I like how you are sitting so tall and steady," giving a thumbs-up, or providing a cue card that says "Nicely done."

Praxis

Kristen M. Powers

Coordinator of Rehabilitative Services, Center for Children with Special Needs, Glastonbury, CT, USA

Synonyms

[Motor planning](#)

Definition

Praxis refers to the brain's ability to develop, organize, and carry out the necessary steps to complete an unfamiliar task or a series of tasks (Ayres 1973). Ayres (1972, 1979) noted that effective motor planning is dependent on an individual's ability to integrate information from the sensory systems, including visual, proprioceptive, vestibular, and tactile stimuli. Three components of praxis have been defined as ideation, planning, and execution (Ayres 1973, 1985). Ideation is defined as generating a plan of action (Parham and Mailloux 2001) and can impact an individual's ability to fluidly perform motor actions, particularly in new situations or with novel materials. Planning and execution further allow the individual to plan and anticipate body movements necessary for action and can incorporate sequencing a series of steps when necessary. Children with autism spectrum disorders may show difficulty within the domain of praxis, resulting in awkward motor execution, poor pretend and imaginative play skills, and compromised sequencing abilities for new and novel situations.

Pre-, During, and Posttest Design

► Qualitative Versus Quantitative Approaches

Precentral Gyrus

Susan Y. Bookheimer
Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA, USA

Synonyms

[Brodmann's area 4](#); [Motor cortex](#); [Primary motor cortex](#)

Definition

The precentral gyrus (PCG), also known as the motor strip or primary motor cortex, is the part of the brain's neocortex responsible for executing voluntary movements. This gyrus is located in the most posterior portion of the frontal lobe, lying immediately anterior to (in front of) the central sulcus, and extending from the apex of the brain down to the sylvian fissure, which delineates the temporal lobe. Histologically, neurons in the precentral gyrus have a similar architecture and are denoted as Brodmann's area 4. The

functional organization of the PCG follows a topographical representation of an inverted homunculus (small human), such that the head and face regions are represented at the lowermost portion of the gyrus, the body and limbs extend toward the upper part of the gyrus, and the feet "dangle" over the apex of the brain. Areas of increased fine motor dexterity, especially the lips, tongue, and hands, have a far more extensive representation on the motor strip, while areas with little motor dexterity such as the torso have a minimal motor representation. In motor cortex, the left hemisphere controls the right side of the body and right brain controls the left body. Lesions to the motor cortex will result in an inability to move that portion of the body represented in the homunculus.

While there is little evidence that primary motor cortex plays a key role in autism, there is some evidence of motor cortex abnormalities. Behaviorally, many individuals with autism have motor deficits (e.g., Jansiewicz et al. [2006](#)), though other brain regions such as pre-motor cortex, cerebellum, and basal ganglia may contribute to these deficits. Several brain imaging studies in autism have found differences in precentral gyrus morphology including increased white matter (Mostofsky et al. [2007](#); Mengotti et al. [2011](#)) and decreased cortical thickness (Cauda et al. [2011](#); Scheel et al. [2011](#)). Decreased connectivity between motor cortex and cerebellum during motor performance (Mostofsky et al. [2009](#)) may indicate that motor abnormalities in autism may reflect a deficit in how brain areas involved in movement coordinate their activity.

- on frequency data (Merbitz et al. 2004a). More specifically, precision teaching requires that instructors set a specific measureable and observable goal, select a method of instruction, conduct daily assessments of the learner's performance, and chart the number of correct and incorrect responses on a standard celeration chart. The core strength of precision teaching lies in the scientific rigor that it brings to the field of education (Kubina and Yurich 2009). Teachers have the opportunity when using this approach to observe, describe, record, and analyze a behavior, allowing them to make informed decisions concerning the effectiveness of the current method of teaching. This constant progress monitoring and charting provides the instructor with an easy-to-read, graphic representation of the learner's progress that can be used to develop an effective instructional program. If the student is learning at a rate that allows him or her to reach the set goal in the specified time frame, the instructor can conclude that the current instructional strategy is effective and continue with that program. If the learner is not progressing at the desired pace, the instructor can supplement or change the instructional strategy in an attempt to facilitate the learner's progress (Kubina and Yurich 2009). Precision teaching can be used with and is believed to enhance the efficacy of a wide variety of educational or treatment programs (Johnson and Street 2012; Kubina and Yurich 2009; Lindsley 1992).

²Claremont Graduate University, Claremont, CA, USA

³Trumpet Behavioral Health, Lakewood, CO, USA

Definition

Precision teaching is a behavioral evaluation method for instruction and curricula that focuses

Historical Background

Ogden Lindsley and his colleagues began developing precision teaching in the 1960s (Lindsley 1964). At this time, behavioral techniques (e.g., schedules of reinforcement and punishment, response shaping, stimulus control) were commonly used in educational settings (Lindsley 1964). While generally effective, these strategies did not allow all students to reach the desired level of achievement.

Instead of focusing on specific behavioral techniques, Lindsley applied behavioral measurement and charting procedures to educational programs (Binder and Watkins 1990; Lindsley 1964).

More specifically, Lindsley and his colleagues used assessments of active and observable behavior, frequency counts, and charting to examine individual student progress. It was believed that using this behavioral measurement system would provide instructors with the information required to discover an effective instructional strategy for each learner.

Collecting frequency data enabled early precision-teaching researchers to discover the importance of rate of correct responding. Eric Haughton and his colleagues found that both accuracy and speed of responding influenced the acquisition of more advanced skills (Haughton 1980). Based on this finding, precision teaching came to emphasize the importance of learning each skill to fluency, or the accuracy and rate of responding required to make that skill functional (for more information on fluency, please see section “Goals and Objectives”).

Although not widely implemented, educators and researchers continue to develop precision-teaching manuals, tools, and fluency databases. Charting applications are also now available to allow teachers to electronically chart their student’s progress (Johnson and Street 2012). Research on precision teaching is published in *The Journal of Precision Teaching and Celeration* and other peer-reviewed journals.

Rationale or Underlying Theory

Precision teaching is based in the belief that all learners can succeed with the appropriate support. Unlike traditional educational programs, this perspective attributes failure to the program rather than the learner. If a learner is not succeeding, the instructor must change the environment (e.g., the type of instruction, intensity of instruction) to better support learner progress. A central component to the underlying theory of precision teaching is the “Try Again” principle, which states that when a method is not effective, the teacher needs to continue to modify or change the method until the learner is successful at the task (Kubina and Yurich 2009).

Creating appropriate learning environments means that the instructor must know when a

learner is struggling, the environmental variables that were in place, and what changes need to be made. Precision teaching provides a systematic framework for identifying and replacing ineffective teaching strategies. This is believed to facilitate the development of effective programs and learner progress.

Goals and Objectives

Precision teaching is intended to maximize learner progress by monitoring their response to intervention and modifying the instructional strategies as necessary. It is a content-free method of evaluating program effectiveness. As such, it can be and has been used to address a wide range of academic (e.g., reading words, solving addition problems), social (e.g., answering questions, making eye contact), and other (e.g., aggressive behaviors, welding) issues and skills (Kubina and Yurich 2009; Ramey et al. 2016).

Regardless of the program goal, precision teaching recognizes that both the learner’s ability to demonstrate a skill and the time it takes him or her to do so influence his or her ability to use this skill in real-world situations. Therefore, precision teaching emphasizes that the individual learn a skill to fluency, or gains a level of accuracy or quality and speed required to make a skill functional (Fabrizio and Moors 2003; Johnson and Street 2012). Individuals who learn a skill to fluency are more likely to retain the skill following intervention; engage in the skill long enough to complete real-world tasks; and demonstrate that skill in new situations, distracting environments, and in combination with related skills (Fabrizio and Moors 2003; Kerr et al. 2003).

Treatment Participants

Precision teaching has been used with a diverse range of learners. This educational method has been implemented in programs involving teaching skills to typically developing, gifted and developmentally disabled individuals (Cavallini et al. 2010; Johnson and Street 2012; Kubina et al. 2009). A focus of current research has

been on the implementation of precision teaching to interventions for individuals with autism. (Johnson and Street 2012; Kubina and Yurich 2009; Ramey et al. 2016).

Autism treatment programs have implemented precision teaching with students as a way to track each individual's progress and to evaluate the effectiveness of the students' current treatment plan. The daily assessment and charting of the learners progress allow for the teacher to be aware of any adjustments that need to be made in a timely manner (Kubina and Yurich 2009; Merbitz et al. 2004b). Individuals with ASD often fail to maintain the learned behaviors over time or apply them to different settings. Precision teaching's emphasis on fluency (see section "[Treatment Procedures](#)" for more detail) addresses these common issues (Kubina et al. 2002).

It has been suggested that it may be particularly important to use precision teaching with lower-functioning individuals (Merbitz et al. 2004b). By definition, these individuals are further behind their peers and are especially in need of effective instruction if they are to reach the normative level of achievement. More information is needed to identify individual characteristics associated with rate of learner progress.

Treatment Procedures

Precision teaching is an ongoing process of goal setting, assessment, charting, and behavioral skills training. The goals, assessments, charts, and program decisions are generally developed and completed by one or more instructors. However, when those receiving the treatment are able, they may assess and chart their own progress and contribute to the goal setting and program decisions (Lindsley 1992). Precision teaching requires that each individual learner has their own goals, assessments, and charts, but has been implemented to whole classes or treatment groups (Lindsley 1992). The main components of precision teaching (pinpointing, counting, and charting) are described below.

Pinpointing

Pinpointing refers to the identification of the targeted behavior. Regardless of the program goal, the instructor should identify an active and observable behavior that can be assessed to monitor learner progress (Kerr et al. 2003). For example, if a program is intended to increase a learner's addition skills, an appropriate measure would be the number of problems the learner correctly answers in 1 min. In other cases, the measureable behavior may be less obvious. For instance, the instructor may be trying to increase a learner's silent reading. The instructor cannot directly measure how many words a learner reads silently and will have to develop a less direct behavioral measure. The instructor may ask the learner to answer questions to determine his or her comprehension of the silently read passage (White 1986).

In pinpointing the targeted behavior, the instructor must select a learning channel. The learning channel refers to the type of instruction the individual receives and the type of response he or she is expected to demonstrate (Kerr et al. 2003). For example, an individual's program intended to increase the learner's vocabulary could use a hear/give or see/say learning channel. The learning channel hear/give could involve the instructor saying a word and the individual giving the instructor the corresponding picture, while the learning channel see/say would involve the instructor showing the individual the picture and the individual verbally labeling it. Other learning channels include hear/do, hear/say, see/do, and see/match (Fabrizio and Moors 2003; Kerr et al. 2003).

These different learning channels allow teachers to select the learning channel that best facilitates a particular individual's learning style. This may be especially relevant to the development of effective programs for individuals with autism, who do not always have the speech or academic skills required to say or write answers (Kerr et al. 2003).

Once the learning channel is established, the instructor must define the program goal and the correct and incorrect responses. Because of precision teaching's emphasis on fluency (see section

“Goals and Objectives”), goals are stated as a frequency aim (i.e., the number of correct responses within a unit of time) that is likely to lead to skill application, maintenance, endurance, stability, and generalization (Johnson and Street 2012). Researchers have compiled a database of frequency aims that have been associated with retention, endurance, stability, and application across a range of skills for individuals with autism (Fabrizio and Moors 2003). Although there is individual variability, instructors can consult this and other databases when developing frequency aims.

Counting

Progress is monitored by counting demonstrated behavior. The instructor selects a teaching strategy and a teaching time (e.g., discrete trial training for 15 min a day) and an assessment period (e.g., 1 min). The learner receives the instruction and then participates in an assessment. During the assessment period, the learner is given the opportunity to demonstrate the targeted behavior, and the instructor counts the number of correct and incorrect responses. Unlike traditional percent correct measures, counting the number of correct and incorrect responses allows the instructor to determine the accuracy and frequency of response.

Charting – The Standard Celeration Chart

Instructors monitor learner progress with standard celeration charts, which have days along the x-axis and frequency counts along the y-axis. In other words, a change from 10 to 20 correct responses looks the same as the change from 20 to 40. Each day, the instructor marks the number of correct and incorrect responses demonstrated during the assessment period.

The **standard celeration charts** differ from other measurement instruments because of the implementation of a ratio scale, as opposed to an equal interval scale, for measuring frequency (Johnson and Street 2012). Using a ratio scale allows for teachers to measure the learner’s relative change, or growth, over time (Johnson and Street 2012). On standard celeration charts, the frequency count axis is scaled to show changes

in the rate of progress instead of number of responses. This means that a change of 10–20 will look the same as a change of 20–40 because the individual has doubled their performance in both cases (Kubina et al. 2002).

Regularly charting learner performance in this way provides teachers with a clear picture of learner progress. If the chart shows a steep and steady rate of learning, the instructor can conclude that the existing program is sufficient. However, if the individual’s progress flattens or will not allow the individual to meet his or her goal by the established timeline, the instructor should modify the program to better facilitate learning.

Efficacy Information

There is evidence that precision teaching increases learner progress with typical, low-performing, and developmentally disabled students. A commonly referenced series of pivotal studies in the field were conducted in Great Falls, Montana. These studies found that typical and low-performing elementary and high school students who were taught with precision teaching tend to make more progress and score higher on measures of math and writing skills than assigned or matched control groups (White 1986).

Current research in the field has found similar results concerning the benefits of using precision teaching with participants ranging from elementary school students to graduate university students (Kubina et al. 2009; Lydon et al. 2017). A study conducted in Pennsylvania with over 200 students found a positive effect on the reading skill development of low-performing elementary school students when they were taught word reading skills through a direct instruction reading program combined with precision teaching (Kubina et al. 2009). Another study involved using precision teaching to enhance medical students’ procedural skills. The researchers found that the medical students who were taught with the simulation-based intervention that involved precision teaching demonstrated higher accuracy

with their performance of the skill compared to the control groups (Lydon et al. 2017).

There are a number of case studies indicating that individuals with disabilities including learning disabilities and ASD do make progress and meet set goals when their instructors use precision teaching strategies (Lolich et al. 2012; Schirmer et al. 2007; Travis et al. 2012). A few more extensive and methodologically rigorous research has also provided support for the potential of implementing precision teaching with individuals with ASD (Ramey et al. 2016; Weiss et al. 2008). Weiss et al. (2008) examined archival data on the skill maintenance and frequency building of 38 individuals with ASD. This study was the first published data set that supported the efficacy of skill interventions using precision teaching to increase the frequency of responses in children and adults with autism (Weiss et al. 2008).

Ramey et al. (2016) provided additional support for integrating precision teaching into interventions with individuals with autism and other developmental disabilities. This article provided a systematic review of 55 studies that all incorporated the use of precision teaching when targeting skill acquisition in individuals with developmental disabilities. The authors evaluated the empirical support of the precision teaching approach using the National Autism Center's 2009 (2015) National Standards Report guidelines, which has recently been updated to the National Standards Project, Phase II (2015). These guidelines classify treatment interventions into four categories: ineffective/harmful, unestablished, emerging, and established. Ramey et al. (2016) stated that according to these standards, precision teaching is currently classified as an emerging treatment for teaching a wide range of skills to individuals with autism. More high quality studies demonstrating the beneficial effects of precision teaching with this population are needed before it can be classified as an established treatment.

Outcome Measurement

Individual performance is measured via frequent assessments (Johnson and Street 2012; Kubina

and Yurich 2009). These assessments are specific to the targeted skill (e.g., if the targeted skill is labeling objects, the assessment will only measure the learner's labeling of objects). Data from each are charted on the previously described standard celeration charts and provide a graphic representation of the learner's progress (see section "Treatment Procedures" for more detail). For more general indicators of learner progress, instructors can use validated and appropriate assessment tools.

Qualifications of Treatment Providers

Precision teaching can be utilized by general and special education teachers, clinicians, para-professionals, or any other individual attempting to teach skills. There are a number of resources available to individuals interested in learning and implementing precision teaching, including treatment manuals, workshops, and fluency databases (e.g., Kubina and Yurich 2009; Lindsley 1992). There are no training, credentials, or licensure requirements for individuals implementing precision teaching.

Predictive Value of Screening Measures

Michele Villalobos

The Edward Zigler Center in Child Development and Social Policy, Yale Child Study Center, New Haven, CT, USA

Definition

The predictive value of a screening instrument refers to the accuracy of a screening measure. It measures whether an individual actually has a disease. The predictive value can be positive or negative. A positive predictive value (PPV) refers to the percentage of people who screen positive for the condition who actually have the condition. Whereas, the negative predictive value (NPV) is the percentage of people who screen negative for the condition and do not have the condition. The predictive value of screening instruments is determined by sensitivity, specificity, and prevalence of a condition.

Predictors at Toddlerhood for Long-Term Severity of ADHD Symptoms in Autism Spectrum Disorder

Ditza A. Zachor¹ and Esther Ben-Itzhak²

¹The Autism Center/Alut, Department of Pediatrics, Shamir (Assaf Harofeh) Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Zrifin, Israel

²Bruckner Center for Research in Autism, Department of Communication Disorders, Ariel University, Ariel, Israel

Definition

Characteristics among toddlers with autism spectrum disorder that predict adolescent attention deficit/hyperactivity symptom severity.

Historical Background

Autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are two of the most common neurodevelopmental disorders, affecting approximately 2% and 7%, respectively (Lyall et al. 2017; Willcutt 2012), of the general population. ASD and ADHD share an overlapping genetic load (Rommelse et al. 2010), and both disorders show a high occurrence in the family and have male predominance (Musser et al. 2014). ASD is defined by social communication deficits and restricted and repetitive behaviors (RRB) [American Psychiatric Association (APA) 2013], while ADHD is characterized by symptoms of inattention, impulsivity, and hyperactivity (APA 2013). Both disorders have significant long-term, multi-domain impairments; thus, early identification is critical for ASD and for ADHD.

ADHD is the most common comorbidity diagnosed in children and adolescents with ASD (59% to 83%) (van der Meer et al. 2012). Previous studies have examined the presence of ADHD symptoms in ASD, describing more severe ASD symptoms, higher rates of cognitive impairment,

more deficits in adaptive skills, a negative effect on family life, and lower quality of life in individuals with ASD and ADHD in comparison to ASD alone (Avni et al. 2018; Sikora et al. 2012; Sprenger et al. 2013).

Some researchers consider ADHD in the context of ASD as two different phenotypes (ASD alone vs ASD + ADHD), while others propose that within the ASD spectrum, ADHD is a less severe subtype (van der Meer et al. 2012).

Recognizing significant ADHD symptoms in children and youth with ASD has important clinical implications. This allows for a variety of pharmacological and non-pharmacological interventions for ADHD that differ from those for ASD alone. When ADHD is identified in school-aged children with ASD, it allows for the implementation of psychoeducational rehabilitation for those with inattention and executive function deficits, which may affect academic achievement (Happé et al. 2006). For those with behavioral difficulties resulting from hyperactivity and impulsivity symptoms, behavioral interventions that are the mainstay intervention in ADHD can be applied to individuals with ASD to improve their functioning. Target areas can include psychoeducation – encouragement and structure, working memory and cognitive flexibility training, classroom modifications, and developing strategies to handle daily living challenges. In addition, classroom and behavioral modifications, along with self-regulation strategies, are all evidence-based elementary school interventions for managing ADHD and can be applied to ASD + ADHD. Targeted behavioral interventions for ASD and ADHD, such as parental management training to improve the severity of ADHD symptoms, had a positive correlation with the improvement of ASD symptom severity (Manohar et al. 2018). In contrast, failure to recognize or late recognition of ADHD can seriously impact educational and social functioning, worsen mood dysregulation, and increase the occurrence of disruptive behaviors (Biederman et al. 2014).

Thus, finding predictors at toddlerhood for the later occurrence of ADHD symptoms and early identification of ADHD in children diagnosed with ASD is of great importance.

Current Knowledge

One long-term follow-up study on a population diagnosed with ASD at toddlerhood investigated the frequency of elevated ADHD symptoms and the characteristics of those with ASD and ADHD. In addition, the study searched for toddler characteristics that may predict ADHD symptom severity at adolescence (Zachor and Ben-Itzhak 2019). This study included 65 participants, 60 males and 5 females (mean age = 13:8y), diagnosed with ASD at toddlerhood (prior to age 38 months). At the time of diagnosis, the children underwent a comprehensive assessment that included behavioral, cognitive, and adaptive skills and neurological assessments. Diagnosis of ASD was based on results of standardized tests for ASD and on clinical judgment. At follow-up, after 8–16 years (mean, 11:7y), extensive evaluations of cognitive ability, adaptive skills, autism severity, and ADHD symptoms using standardized tests were performed. Participants were divided into two groups with the comorbidity (ADHD+; $n = 39$) and without (ADHD-; $n = 26$). The ADHD+ group included participants who met the cutoff scores according to both parents and teachers on a standardized ADHD questionnaire (Conners 3; Conners et al. 2011) on at least one scale and those who received medication for ADHD. This

longitudinal study found high frequency (60%) of elevated ADHD symptoms in adolescents diagnosed with ASD at toddlerhood as reported in previous studies on ADHD comorbidity in ASD (Avni et al. 2018; Murray 2010). This longitudinal study found that adolescents with elevated ADHD symptoms diagnosed at toddlerhood with ASD showed a more impaired clinical presentation. Having ASD and elevated ADHD symptoms was characterized by more severe ASD symptoms in social communication and RRB domains (Autism Diagnostic Observation Schedule-2 (ADOS-2); Lord et al. 2012), as assessed by professionals (Fig. 1) and reported by parents (Social Responsiveness Scale (SRS); Constantino and Gruber 2012) (Fig. 2). In addition, the group with ASD and elevated ADHD symptoms had lower cognitive ability overall and specifically lower verbal comprehension, perceptual reasoning, working memory, and processing speed (Wechsler Intelligence Scale for Children WISC-IV-; Wechsler 2010) (Fig. 3). It is worth noting that more than half of the participants with elevated ADHD symptoms had IQ scores in the intellectual disability (ID) range. The ASD and ID comorbidity may explain the more severe clinical presentation in autism severity and adaptive skills. In addition, having ASD and ADHD resulted in more impaired communication and

scores (CSS) in social affect (SA-CSS) and RRB (RRB-CSS) domains in adolescents with ASD with and without ADHD (assessed by professionals)

Predictors at Toddlerhood for Long-Term Severity of ADHD Symptoms in Autism Spectrum Disorder, Fig. 2 Autism severity as measured by the Social Responsiveness Scales (SRS-2) scores in social communication and repetitive and restricted interests behaviors (RRIB) in adolescents with ASD with and without ADHD (completed by parents)

Predictors at Toddlerhood for Long-Term Severity of ADHD Symptoms in Autism Spectrum Disorder, Fig. 3 IQ scores in adolescents with ASD with and without ADHD

social functioning (Vineland Adaptive Behavior Scales (VABS); Sparrow et al. 2005) (Fig. 4). These findings supported previous studies that compared individuals with ASD alone to those with ASD and ADHD. These studies reported greater autism severity and more impairments in verbal and nonverbal abilities, spatial working memory, response inhibition, executive functions, and adaptive functioning in all the VABS subdomains for those with ASD and ADHD (Rao

and Landa 2014). Overall, these findings suggest that having elevated ADHD symptoms is characterized by mild global deficits in functioning that affect individuals with ASD. In the above long-term follow-up study, a large portion (87%) of the population with ASD with elevated ADHD symptoms used medication regularly, mainly antipsychotics and stimulants, and about 20% used SSRIs regardless of the severity of the ADHD symptoms (Zachor and Ben-Itzhak

Predictors at Toddlerhood for Long-Term Severity of ADHD Symptoms in Autism Spectrum Disorder, Fig. 4 Adaptive skills scores measured by the Vineland

Adaptive Behavior Scales (VABS) in adolescents with ASD with and without ADHD

2019). This frequency is higher than the medication adherence rates of 57.1–71.4% for individuals diagnosed with ADHD without ASD in the general population (Gajria et al. 2014). It is possible that having both ASD and elevated ADHD symptoms that significantly impact functioning encourages the use of medication to improve certain behavioral symptoms.

In light of the high prevalence of ADHD in the general population and more so in ASD, an important research question is if there are early characteristics that may precede later occurrence of ADHD. Only a handful of studies have examined predictors in infants in the general population that may later be associated with an ADHD diagnosis. Early temperamental differences, such as reduced inhibitory control and attention, increased activity level, and more negative affect were documented in infants at risk for ADHD (Sullivan et al. 2015). Lower developmental quotient at 15- and 24-month follow-ups and a lower receptive language level at 36 months were associated with the reported severity of ADHD symptomatology in third grade (Arnett et al. 2013). Regulation and temperament challenges at 6–36 months of age were related to elevated parent-rated ADHD symptoms in first grade (Willoughby et al. 2017). However, since the diagnostic outcomes of participants in these studies were not known,

it was not clear which infant behaviors would predict a later diagnosis of ADHD. Another study identified several risk factors that were associated with the severity of ADHD symptoms in children with ASD with a mean age of 7:6 years. These variables included motor delay, history of enuresis and allergies, intellectual disability, and a family history of intellectual disability and psychosis (Lamanna et al. 2017).

Regarding ADHD in ASD, only one study so far has specifically examined variables in toddlers diagnosed with ASD that predict severity of ADHD symptoms in adolescence (Zachor and Ben-Itzhak 2019). This prospective study followed a cohort diagnosed with ASD at toddlerhood to adolescence and focused on the association between early cognitive and adaptive skills and ASD symptom severity in toddlerhood and the severity of ADHD symptoms in adolescence and searched for variables in toddlerhood that may predict the severity of ADHD symptoms in adolescence. More severe ASD symptoms in social affect and RRB domains as assessed by professionals (ADOS-2) and lower communication adaptive skills (VABS) in toddlerhood correlated with more severe inattention and hyperactivity/impulsivity symptoms (Conners 3) in adolescence. In addition, lower social adaptive behavior skills in toddlerhood were associated

with more severe hyperactivity/impulsivity symptoms in adolescence. When examining the contribution of cognitive ability, autism severity, and adaptive skills variables assessed during the toddler years for the prediction of later ADHD symptom severity, the severity of restricted and repetitive behaviors (RRB) predicted the severity of inattention and hyperactivity/impulsivity symptoms at adolescence. In addition, early overall adaptive skills predicted the severity of later hyperactivity/impulsivity symptoms.

Although ADHD is diagnosed routinely and more definitively in school-aged children, these findings of more severe RRB and poorer adaptive skills in toddlers diagnosed with ASD may represent early red flags for the later development of elevated ADHD symptoms.

Several studies found a strong association between hyperactive-impulsive ADHD traits and RRB at evaluation time. At the phenotypic level, inattention symptoms correlated with severity of RRB and with social interaction and communication deficits, whereas hyperactivity/impulsivity symptoms were more strongly associated with RRB (Ghirardi et al. 2019).

Anatomical and physiological changes in specific brain structures (basal ganglia, striatum), abnormal connectivity pathways, as well as neurotransmitter dysfunction may be associated with RRB in ASD (Abbott et al. 2018).

Several conclusions can be drawn from these studies. First, clinicians who diagnose ASD in toddlers should pay special attention to red flags such as severe RRB and poor functioning as early prognostic signs for later elevated ADHD symptoms, which should be followed closely. Second, the importance of evaluating symptoms of ADHD in ASD is emphasized as this comorbidity is very common in ASD. In particular, it is important to pay special attention to the presence of severe ADHD symptoms in populations with ASD and a more severe clinical presentation. Finally, there is a negative impact of having elevated ADHD symptoms in addition to ASD. Lower cognition, more debilitating ASD symptoms, and poorer adaptive skills in ASD with ADHD result in more challenging needs. Therefore, comprehensive medical, behavioral, and academic interventions and close follow-up are crucial for

adolescents with ASD who present with elevated ADHD symptoms. It will be important to implement interventions for those with ASD and ADHD to decrease inattention/impulsivity related difficulties, which may likely have a beneficial effect on social functioning. The same applies to the treatment of hyperactivity, which may lessen repetitive behaviors. Pharmacological and behavioral treatments that are known to improve ADHD symptomatology may also prove beneficial in ASD symptom severity and functioning.

Future Directions

The findings described above suggest abnormalities in specific brain regions and connectivity pathways, as well as neurotransmitter dysfunction, occur in both ADHD and RRBs. Combining this common neurobiological basis and the behavioral findings with the strong association between RRB and elevated ADHD symptoms may in the future create a basis for developing possible methods of intervention.

In light of the early predictors found at toddlerhood for later occurrence of elevated ADHD symptoms, it is important to develop early focused intervention to reduce RRB levels in toddlers with ASD and target adaptive skills deficits as early as possible. In future research, it will be important to examine whether these early interventions improve the severity of ADHD symptoms in adolescence.

In addition, it is important to explore early predictors for other comorbidities, such as anxiety and depression, two common disorders in ASD. It will also be important to search for other variables, including family characteristics and early behaviors such as emotion dysregulation and maladaptive internalizing/externalizing behaviors, which may predict or be associated with a later occurrence of elevated ADHD symptoms.

The high prevalence of ADHD in ASD, its impact on functioning, and the high adherence to medication require further examination of the effectiveness of known classes of drugs designed to treat ADHD is required. In addition, searching for a new, more effective drug for this special phenotype of ASD with elevated ADHD

symptoms and evaluating the effect on symptom severity of both disorders are highly needed.

In sum, ADHD symptoms are very common in ASD. Adolescents diagnosed at toddlerhood with ASD with elevated ADHD symptoms at adolescence have lower cognitive and adaptive skills and more severe autism symptoms. Early toddler behaviors, such as more severe restricted and repetitive behaviors (RRB) and lower overall functioning, predict the severity of ADHD symptoms in adolescence. Early awareness of red flags for ADHD in ASD and consequently providing focused interventions in various developmental and functional domains will improve the well-being and functioning of adolescents with ASD and ADHD.

Predictors of Clinician Certainty in the Diagnosis of Autism

Christina G. McDonnell¹ and Elizabeth A. DeLucia^{1,2}

¹Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

²Yale Child Study Center, New Haven, CT, USA

Definition

Clinician certainty is one aspect of diagnostic decision-making that refers to how sure clinicians

are that their diagnosis of autism spectrum disorder (ASD) was accurate. In other words, when clinicians decide to make a diagnosis of ASD, how sure are they that the diagnosis is correct and that the individual truly has autism?

Historical Background

Early and accurate diagnosis of autism spectrum disorder (ASD) is a critical healthcare priority, as earlier identification of ASD facilitates earlier entry into intervention services that increase the likelihood of positive developmental trajectories across the lifespan (Fountain et al. 2012). Earlier identification of ASD is also linked with increased family satisfaction with the diagnostic process (Crane et al. 2016). Thus, the need for timely diagnosis of ASD is imperative.

However, timely identification of ASD continues to be challenging, and the process of obtaining a diagnosis is fraught with difficulties for individuals and their families. For example, although symptoms of autism can be observed as early as infancy and reliable diagnoses can be made before age 3 (Guthrie et al. 2013), the majority of individuals are not identified with ASD until school age or later (Shattuck et al. 2009). Moreover, a growing number of individuals are receiving a diagnosis of ASD for the first time in adulthood, missing opportunities throughout their childhood and adolescence for adequate support and self-understanding. Importantly, there are disparities in access to early diagnosis, as child sex, socioeconomic status, and race/ethnicity all predict the timeliness of receiving an autism diagnosis (Nowell et al. 2015). Given these difficulties, it is unsurprising that the majority of caregivers and individuals seeking an ASD diagnosis report being highly dissatisfied with the diagnostic process.

Clinician difficulty in assessing and diagnosing ASD with certainty may be one factor contributing to challenges in the diagnostic process, as there is no singular “test” for ASD. Rather, ASD is a complex, heterogeneous neurodevelopmental disorder for which differential diagnosis can be difficult (Matson et al. 2012). Typically, best practice ASD assessment

involves integrating information from a number of sources that may yield conflicting results, including self-report, caregiver report, teacher report, observation, and performance on standardized tests (Kim and Lord 2012). Although standardized screening and assessment instruments have greatly improved our ability to identify and discriminate ASD, these measures do not have perfect sensitivity and specificity. Even very experienced clinicians using standardized assessment instruments may ultimately be uncertain regarding an individual's diagnosis, which could lead to delays in making a final diagnosis. The current entry first reviews current knowledge on clinician certainty, summarizes predictors of clinician certainty, and concludes with future directions for this critical area of study.

Current Knowledge

What is clinician certainty? Clinician certainty is one aspect of diagnostic decision-making that refers to how sure clinicians are that their diagnosis was accurate. In other words, when clinicians decide to make a diagnosis of ASD, how sure are they that the diagnosis is correct and that the individual truly has autism? Prior work has conceptualized clinician certainty using dichotomous (“I am absolutely certain about this diagnosis” versus not) and continuous (e.g., ranging from “absolutely certain not ASD” to “absolutely certain ASD”) rating scales (Hedley et al. 2016; McDonnell et al. 2019). Clinician certainty expands upon the construct of “frank presentations” of ASD, which refers to the phenomenon wherein clinicians can recognize distinctive behavioral presentations characteristic of ASD almost immediately (de Marchena and Miller 2017).

Levels of clinician certainty. Preliminary research suggests that a significant portion of ASD diagnoses are made with some level of uncertainty. Among a sample of young children referred for ASD diagnostic evaluations, 40% of diagnoses were made with some level of uncertainty (McDonnell et al. 2019). Such lack of certainty may negatively impact the diagnostic

process. For example, if clinicians are uncertain regarding the accuracy of an ASD diagnosis, there may be longer latencies to making a final diagnosis, and families may be less receptive to the diagnosis and its associated treatments. Thus, understanding factors that predict clinician certainty can identify individuals at risk for under-identification, prolonged diagnostic pathways, and negative diagnostic experiences and can also aid in targeting efforts designed to improve assessment processes.

Sex and clinician certainty. A range of demographic factors may relate to clinician certainty, including child sex, age, and broader family-level demographic factors. There has been much interest in understanding how to improve diagnostic practices among females given growing evidence that the disproportionate ratio of males to females diagnosed with ASD is partially due to a diagnostic sex bias (Loomes et al. 2017). Females with ASD may be under-identified due to difficulties identifying the female autism phenotype, which may be more subtle than presentations characteristic of males (Lai et al. 2017). Providers and parents consistently cite difficulties with the diagnostic process for females (Mademtzi et al. 2018; Penner et al. 2017), and an increasing number of women do not receive their diagnosis until late adolescence or adulthood (Bargiela et al. 2016). However, recent work has not found that clinician certainty relates to child sex (McDonnell et al. 2019). Future research is needed in this critical area of study to examine diagnostic decision-making for females presenting with symptoms of ASD.

Age and clinician certainty. Child age may also relate to clinician certainty in the diagnosis of ASD, although research findings are mixed. One study using a sample of youth under age 6 reported that clinicians were most certain when diagnosing the youngest children (McDonnell et al. 2019). It is possible that certainty is higher for the youngest children, because children who are already being seen for a diagnostic evaluation at a young age likely present with the most severe and/or obvious symptoms. Moreover, as children get older, differential diagnosis may become more complicated as clinicians increasingly need to consider a child's behavior in multiple settings and rule out

a range of behavioral, emotional, and developmental diagnoses. However, other research has not found an association between age and diagnostic certainty (Hedley et al. 2016), emphasizing the need for future research in this area.

Demographics and clinician certainty. Diagnostic certainty may also relate to broader sociodemographic characteristics. Strikingly, children's insurance status has been linked with clinician certainty, with diagnostic certainty over two times more likely for children on private compared to public (Medicaid) insurance in the United States (McDonnell et al. 2019). It is important to note that this finding held even when controlling for other demographic factors and the level of autism symptoms reported on gold standard measures such as the Autism Diagnostic Observation Schedule (ADOS), supporting that insurance status plays a significant role in diagnostic decision-making. This suggests that clinician judgment may be influenced by socioeconomic status (SES), as insurance status is one broad indicator of SES that relates to race, parental education, and family income. Thus, finding that Medicaid status was linked with lower diagnostic certainty extends a large body of work demonstrating disparities in autism identification among racially diverse and/or lower SES children (Nowell et al. 2015; Fountain et al. 2012). Future research aimed at explicating *why* diagnostic certainty relates to indicators of SES is essential for reducing healthcare disparities in this area.

Clinical characteristics and clinician certainty. Diagnostic certainty also relates to the ultimate diagnostic conclusion made by the diagnostician as well as to clinical characteristics of the individual presenting for an evaluation. Clinicians are much more likely to report being certain when they confirm that a diagnosis of ASD is present, compared to when they rule out ASD in favor of another or no diagnosis. In one study, 70% of diagnoses were classified as certain when a diagnosis of ASD was made, compared to only 30% when a diagnosis of ASD was not made (McDonnell et al. 2019). This indicates that it is easier for clinicians to positively identify ASD compared to ruling it out and suggests that clinicians are likely to detect some behaviors or

symptoms of autism even among children not diagnosed with ASD. Clinician certainty has also been related to level of autism symptoms, with certainty the lowest for those presenting with a moderate level of symptoms relative to those presenting with high or minimal symptoms (McDonnell et al. 2019). Higher clinician certainty also relates to lower IQ, suggesting that diagnostic decision-making may be more uncertain for children with higher levels of cognitive abilities (Hedley et al. 2016).

Parent report and clinician certainty. When considering a diagnosis of autism spectrum disorder, clinicians are advised to take information from multiple sources, such as parents, teachers, and clinical observation, into account. As a result, the degree to which informants agree on ASD symptoms is a relevant factor in the prediction of clinician diagnostic certainty. Evidence suggests only a moderate level of agreement between parents' report of ASD symptoms and clinicians' observed symptoms. Several studies find modest agreement between the ADOS, the gold standard clinician-administered diagnostic measure, and the ADI-R, a gold standard parent diagnostic interview. For example, de Bildt et al. (2004) note only fair agreement between the ADOS and the ADI-R, with agreement being higher for children ages 5–8 than older children. Similarly, in a study of 12-month-old infants at high- and low-risk for developing ASD, Macari et al. (2018) found a moderate agreement between parent report of ASD symptoms and clinician observation ($r = 0.34$). Another study found no relationship between the ADOS severity score and parent ratings on the Social Responsiveness Scale (SRS; Reszka et al. 2014). Given that clinician ratings and parent reports do not tend to be highly correlated, it is important to consider how clinician diagnostic certainty may be impacted by a contrasting parent report.

Teacher report and clinician certainty. It is also important to consider how teacher reports of ASD symptoms relate to parent or clinician accounts, given the importance of the school system in identifying and providing services for children with ASD. In a study of children ages 1–12 years by Mayes and Lockridge (2018),

mother, teacher, and psychologist reports on the Checklist for Autism Spectrum Disorders were compared. Although psychologists rated children with ASD as having more symptoms than did mothers or teachers, there was a high degree of correlation between mother and psychologist reports. However, mother-teacher and psychologist-teacher reports were not correlated. Similarly, another study found only a small to moderate correlation (weighted $r = 0.27$) between parent and teacher reports of social skills in children with ASD and/or intellectual disability (Stratis and Lecavalier 2015). Interestingly, a third study found a correlation of 0.418 between the teacher-rated SRS and the ADOS severity score, reflecting the necessity of additional work in this area (Reszka et al. 2014). It is important to consider the effect that informant discrepancy may have on clinician certainty. Disagreement between parents, teachers, and clinicians may impact the degree of uncertainty that clinicians feel during the diagnostic process. As such, it is critical that future research examines the effects of informant discrepancy in depth, with a particular emphasis on its relationship with clinician certainty.

Future Directions

Future research on the process of diagnostic decision-making in the context of ASD, including ongoing assessment of predictors of clinician certainty, has the exciting potential to advance our understanding of the nature of ASD as a disorder and also improve the diagnostic process. First, research on diagnostic certainty can advance our understanding of the nature of ASD. Recent debates about how to best conceptualize psychopathology have emerged in the adult and childhood psychopathology literatures (Kotov et al. 2017). For example, to what extent should psychological disorders be characterized as discrete categories versus continuous dimensions? Although autism has been minimally considered within this debate, ASD has increasingly been understood as a spectrum wherein characteristics of ASD are present to a certain extent even within

the general population (Lord and Jones 2012). Understanding how clinicians perceive and diagnose ASD has the potential to inform this ongoing debate. For example, finding that clinicians tend to be at least moderately certain when positively identifying ASD yet are very *uncertain* when ruling it out suggests that requiring a categorical decision (e.g., a child either has ASD or does not) may be quite difficult and may not adequately capture the nature of presenting autism symptoms.

Second, the limited body of work on diagnostic certainty thus far highlights the pressing need for ongoing research into improving the diagnostic process. It is alarming that children's health insurance status predicts clinician certainty even when clinicians have access to results from standardized assessment results such as the ADOS. Understanding how clinicians perceive autism symptoms in diverse cultural groups and *why* diagnostic decisions tend to be more uncertain for families on public-funded insurance programs such as Medicaid is essential for addressing disparities in diagnostic identification. Moreover, why is the overlap between parent and teacher report so small for some youth, and how should clinicians weight reports from different informants when attempting to summarize assessment results into one diagnostic conclusion? Future evaluations of the strength of associations between different assessment methods have important potential in this area. Lastly, much work remains to be done in the area of psychometrics, including developing empirically validated measures that can be disseminated for use by clinicians from all training backgrounds.

Third and finally, how can we improve clinician diagnostic certainty and their skills in differential diagnosis of ASD? Promising approaches have tested the value of providing mentoring and consultation to clinicians remotely over telecommunication, such as the ECHO programs (Mazurek et al. 2019). Expanding these types of training approaches into other healthcare settings, and integrating ASD assessment training universally into graduate training programs, could also prove instrumental in improving clinicians' ability to recognize and diagnose ASD with confidence. Understanding and improving clinician

decision-making in ASD has the potential to increase the timeliness of the diagnostic process and can result in a more positive experience for the youth or adult receiving the diagnosis of ASD. Thus, the overall goal of this research is to reduce disparities in the diagnostic process for underserved individuals and their families so that timely, confident, and more certain diagnoses can be provided equitably for all families.

Predictors of Emotion Regulation in Children with Autism Spectrum Disorder (ASD)

Rachel M. Fenning, Jason K. Baker and
Jacquelyn Moffitt
Department of Child and Adolescent Studies,
California State University, Fullerton,
Fullerton, CA, USA

Emotion regulation (ER) involves the ability to understand, monitor, and modulate emotion states in the service of goal-directed activity (Thompson 1994). A number of studies have identified significant challenges with ER in children with ASD relative to children without ASD, including a tendency to use less adaptive and more maladaptive regulatory strategies (Jahromi et al. 2012; Mazefsky et al. 2014; Nuske et al. 2017; Samson et al. 2012, 2015a, b). ER strategies also appear to be less effective in reducing observed negativity for children with ASD than for children with neurotypical development (Jahromi et al. 2012), suggesting problems with strategy selection, utilization, and implementation.

The growing evidence linking ER difficulties with comorbid emotional and behavioral problems in children with ASD (Mazefsky and White 2014; White et al. 2014) has underscored the importance of understanding factors that may predict increased risk for regulatory challenges in this population.

Multiple factors have been conceptualized as underlying problems with ER in children with ASD, though relatively few empirical investigations exist. Core symptoms of ASD as well as associated social-cognitive and executive functioning deficits may contribute to regulatory problems (Jahromi et al. 2013; Mazefsky and White 2014). Mechanisms of effect may be direct (e.g., difficulties with emotion understanding, weak central coherence, or cognitive and behavioral rigidity may challenge regulatory efforts) or indirect (e.g., social communication deficits may impede the delivery of co-regulatory supports from parents, teachers, and others in the child's environment). Interestingly, ASD symptoms have been linked more consistently to global ER quality (Berkovits et al. 2017; Fenning et al. 2018) than to ER strategies (Konstantareas and Stewart 2006; Patel et al. 2017). A recent study revealed ASD symptom severity to be the most significant correlate of observed global dysregulation in children with ASD, predicting above and beyond other child factors, including age, IQ, and sympathetic nervous system activation, and parental co-regulatory behavior (Fenning et al. 2018).

In addition to ASD-related symptoms, child intellectual functioning has been examined in relation to ER. Although most studies have not found significant links between IQ and ER in children with ASD (Berkovits et al. 2017; Samson et al. 2014, 2015a, b; Ting and Weiss 2017), some investigations employing observational ER measures have revealed associations with cognitive functioning (Fenning et al. 2018; Konstantareas and Stewart 2006). However, ER research has predominantly excluded children with ASD who exhibit co-occurring cognitive delays. Recent calls to action have advocated strongly for expanding inclusion criteria to ensure appropriate representation and understanding of the broader population of children with ASD (Fenning et al. 2018; Baker et al. 2019).

Maturation of the autonomic nervous system is believed to contribute directly to ER (Beauchaine et al. 2007). Respiratory sinus arrhythmia (RSA), an index of the parasympathetic nervous system, has emerged as a robust biomarker of ER in children without ASD (Beauchaine 2015). Several studies suggest the potential for altered RSA in children with ASD (see Benevides and Lane 2015 for a review). In addition, individual differences in RSA have been linked with variation in emotion recognition and social skills in this population (Bal et al. 2010; Patriquin et al. 2013; Van Hecke et al. 2009), but limited research has focused on ER specifically (Guy et al. 2014). Preliminary efforts to map certain sympathetic indices such as electrodermal activity to ER have not found in-the-moment associations (Fenning et al. 2018). Further research is needed, including consideration of sympathetic-parasympathetic interactions that may offer insight into complex, multi-system processes (Beauchaine et al. 2007; Buss et al. 2018; Fenning et al. 2019). Other biological factors, including neural circuitry and genetics, undoubtedly play a role as well (Mazefsky and White 2014).

Parenting has long been recognized as a powerful exogenous influence on child ER (Cole et al. 1994; Kopp 1982, 1989; Morris et al. 2007; Thompson and Meyer 2007), but surprisingly little research has examined parental influence on ER in children with ASD. The mere physical presence of parents may promote ER in young children with ASD (Jahromi et al. 2012), and greater observed parent-child reciprocity has been associated with reduced negative emotionality in this population (Hirschler-Guttenberg et al. 2015). Explicit parental co-regulatory efforts have also been linked to the quality of child ER but only when measured concurrently during dyadic parent-child tasks (Fenning et al. 2018; Gulrud et al. 2010; Ting and Weiss 2017). Further research utilizing carefully controlled longitudinal designs is needed to understand the potential influence of parenting on child ER.

Challenges with ER and associated emotional and behavioral problems are well documented in children with ASD. Emerging evidence suggests that these ER difficulties may be related to core

aspects of the disorder (Fenning et al. 2018; Mazefsky and White 2014). However, much remains to be learned about factors underlying risk for poor ER in this population. Understanding the developmental course of ER in children with ASD as well as factors predictive of individual differences in ER trajectories is critical to informing conceptualizations of ASD and to identifying and refining interventions tailored to address ER and related comorbid problems.

Preemployment Skills for People with ASD

Ernst O. VanBergeijk
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University,
Cambridge, MA, USA

Synonyms

Employment readiness skills; Job readiness; Life skills; Prevocational skills; Soft job skills

Definition

Preemployment skills are a set of skills that establish the foundation of employment skills. Conceptually, they are the building blocks of more advanced skills and are essential for an individual on the autism spectrum to master before he or she can be successful in the world of work. These skills are in direct contrast to employment skills which often are job specific. These are often referred to as soft job skills.

Generically, preemployment skills include behaviors such as bathing, grooming, and dressing appropriately for the particular work environment. Related to being able to present oneself professionally in a work environment with clean clothing is the skill of being able to do laundry including washing, folding, ironing, and hanging of clothing. Time management is another example of a generic skill individuals need to master in order to be successful in the work place. Time management for individuals on the spectrum is a cluster of behaviors such as setting an alarm clock or smartphone, waking up on time, arriving on time, and on-time task completion. Being able to navigate and use public transportation is another cluster of preemployment skills individuals on the spectrum should master prior to employment. The majority of individuals on the spectrum will probably not own their own car and learn how to drive. Consequently, learning how to get to and from home and work is paramount. In addition to learning how to get to and from work, the travel training should include how to get to the grocery store, medical provider offices, and retail outlets. The travel training should not be simply fixed route training, but rather, it should center on contingency management, i.e., what to do when things go wrong when using public transportation. Self-advocacy is another pre-employment soft skill that is important for individuals with ASDs to learn especially when dealing with supervisors and co-workers. Financial literacy especially money management, taxes, and budgeting also fall under the heading of preemployment skills.

With the passage of the Workforce Innovation and Opportunity Act (WIOA) in 2014, the federal government now requires state offices of vocational rehabilitation services to provide pre-employment transition services. Previously, state agencies refused to pay for such critical services and training. According to WINTACH (2017) preemployment transition services should include:

- Job exploration counseling
- Work-based learning experiences, which may include in-school or after school opportunities,

experiences outside of the traditional school setting, and/or internships

- Counseling on opportunities for enrollment in comprehensive transition or postsecondary educational programs
- Workplace readiness training to develop social skills and independent living
- Instruction in self-advocacy

Under WIOA 15% of vocational rehabilitation services budgets must be spent on transition services for youth with disabilities, thereby allowing youth with disabilities the opportunity to acquire preemployment skills. As per WINTACH, “Funds reserved for pre-employment transition services may be used for the required, authorized, and pre-employment transition coordination activities.”

Preemployment transition coordination consists of:

- Attending individualized education program meetings for students with disabilities, when invited
- Working with the local workforce development boards, one-stop centers, and employers to develop work opportunities for students with disabilities, including internships, summer employment and other employment opportunities available throughout the school year, and apprenticeships
- Working with schools, including those carrying out activities under section 614(d) of the IDEA, to coordinate and ensure the provision of preemployment transition services
- When invited, attending person-centered planning meetings for individuals receiving services under title XIX of the Social Security Act (42 U.S.C. 1396 et seq.) (WINTACH 2017)

Preference and Reinforcer Assessment

Mariana Torres-Viso¹ and Ryan Knighton^{1,2}

¹The Center for Children with Special Needs, Glastonbury, CT, USA

²Newton Public Schools, Newton, MA, USA

Synonyms

[Forced-choice preference assessment](#); [Free-operant preference assessment](#); [Multiple stimulus with replacement \(MSW\) preference assessment](#); [Multiple stimulus without replacement \(MWSO\) preference assessment](#); [Paired-choice preference assessment](#); [Stimulus preference assessment](#)

Definition

Preference assessments yield information about stimuli that may function as motivators in behavioral programming (Pace et al. 1985). Assessments may include stimuli such as objects, activities, food, or social interactions and can be carried out through indirect and direct methods (Tullis et al. 2011). Examples of indirect methods include interviews, checklists, and rating scales (Green et al.

1988; Windsor et al. 1994) that could be completed by a caretaker or the individual. Direct methods involve structured activities that measure choice or engagement. Choice-based assessments measure preference by having the individual select between two or more stimuli followed by access to the selected stimulus. Engagement-based preference assessments, on the other hand, measure the duration that an individual may spend interacting with a given stimulus. Preference assessments provide a pool of potentially preferred stimuli for the individual, a comparative value or hierarchy of most-to-least preferred stimuli and, for more structured forms of preference assessment (e.g., forced-choice preference assessment), a relative value among the evaluated stimuli (Roscoe et al. 1999).

Reinforcer assessments expand beyond the concept of preference to assess whether a preferred stimulus possesses sufficient value for the individual to increase a specific behavior to contact the stimulus. In other words, reinforcer assessments determine if the individual will work to access a stimulus, thereby identifying the stimulus as a reinforcer rather than a preference. Oftentimes, stimuli assessed in the reinforcer assessment originate from preference assessments. The contrast between these two assessments is an important one for individuals with autism spectrum disorders: stimuli identified as preferred do not always function as reinforcers (DeLeon and Iwata 1996; Pace et al. 1985). That is, although an individual may demonstrate a preference for a given stimulus, it may not carry sufficient value to motivate an individual to complete demands to earn it.

An example of a preference and reinforcer assessment could be as follows: caretakers seek to identify potential reinforcers for a child's reading program. A preference assessment was conducted, which included a rating scale completed by caregivers, followed by direct assessment of the child's choices. Eight items were assessed: dolls, Play-Doh[®], a cartoon video, a coloring book, building blocks, a farm house toy, a hula hoop, and a Slinky[®]. In their rating scales, caregivers identified the Slinky[®], Hula

Hoop[®], and dolls as the most preferred items for their child, in that order. A paired-choice preference assessment conducted with the child yielded the greatest preference value for the coloring book, followed by the dolls and Hula Hoop[®]. Next, a reinforcer assessment was carried out with the child, where he was given 30-second access to each of the top four preferred stimuli after completing a reading task. The reinforcer assessment found that the child was most likely to read to access the Hula Hoop[®] and coloring book, but not the other two items. Based on these evaluations, these reinforcers were incorporated into the child's reading program.

Prefrontal Cortex

Susan Y. Bookheimer
Department of Psychiatry and Biobehavioral
Sciences, UCLA School of Medicine, Los
Angeles, CA, USA

Definition

The term “prefrontal cortex” refers to the part of the brain’s frontal lobe that lies in front of the primary motor cortex and the areas immediately anterior to motor regions, called premotor cortex. The functions of the prefrontal cortex are vast but include the higher cognitive processes such as planning, decision-making, working memory, cognitive control, and response inhibition. These sophisticated brain functions are often called the “executive functions” reflecting the high level decision-making processes performed here. In humans, the prefrontal cortex is more highly developed in all other animals and constitutes the major brain differences between human and nonhuman primates. Damage to the prefrontal cortex will cause many cognitive, behavioral, and personality changes including impulsivity, difficulty in controlling and regulating emotion, problems making good decisions and integrating information, difficulty in organizing information, planning activities, keeping information in one’s mind, generating new thoughts and ideas, flexibility in thinking and behaving, difficulty retrieving information from memory, and problems in time awareness and future directedness. Thus, the prefrontal cortex is often thought of as the part of the brain that makes us most human.

Prelinguistic Autism Diagnostic Observation Schedule

Rhiannon J. Luyster
Department of Communication Sciences and
Disorders, Emerson College, Boston, MA, USA

Synonyms

[PL-ADOS](#)

Description

The PL-ADOS (DiLavore et al. [1995](#)) is a semi-structured evaluation of play, social interaction, and communication skills in young children suspected of having an autism spectrum disorder. It was designed to generate a social context in which behaviors relevant for a diagnosis of ASD may be observed in a clinical setting. The PL-ADOS is intended for children under the chronological age of 6 years and under the developmental age of 3 years; it is aimed specifically toward children who are not yet using phrase speech. It includes 12 activities with 17 accompanying activity ratings along with 31 overall codes. There is an algorithm that includes a subset of codes and generates a binary classification (autism, non-spectrum) based on DSM-IV and ICD-10 criteria. Administration takes approximately 30 min and can be completed in a professional’s office or playroom, although a caregiver is present. Codes are completed immediately after administration and are based on all behaviors during the administration. Scores on

each code generally range from 0 to 2, with higher scores indicating greater abnormality.

Historical Background

The PL-ADOS was developed at a time when early diagnosis of ASD was an emerging field of study. Existing instruments, which were largely intended for older individuals, offered insufficient sensitivity for young nonverbal populations. The ADOS had proved to be a useful instrument to aid in the diagnostic process, and the PL-ADOS modified the ADOS for children with limited language skills. The tasks and administration were adapted to reduce the need for language skills and to make them more suitable for developmentally and chronologically younger children. Moreover, additional activities were created that addressed known areas of difficulty for young children with autism.

Psychometric Data

Instrument development involved both validity and reliability studies. The validity study included 21 children with autism and 42 children with non-autism developmental disorders (21 in a 3-year-old group and another 21 in a 2-year-old group). Nine of 17 activity ratings showed a group effect, successfully discriminating the autism sample from both groups with developmental disorders. The remaining items distinguished the group with autism from only one of the comparison samples or did not differ across group at all. Similar analyses on 31 overall summary codes revealed that the autism sample differed from both comparison samples on all items but five (*overall level of language, tantrums and aggression, functional play, imagination/creativity, showing*). However, the autism sample differed from the 3-year-old comparison sample on the latter three items. As expected, the group of children with autism had a higher average score on all items than the comparison samples.

An algorithm was generated by selecting items that met theoretical and empirical thresholds for optimal group classification. Algorithm items were grouped into two categories: social

interaction/communication and restricted, repetitive behaviors. Algorithm items in each category were summed, yielding two separate algorithm scores. Cutoff scores were then selected based on maximal sensitivity and specificity, with a final cutoff of 12 in social interaction/communication and a cutoff of 2 in restricted, repetitive behaviors.

The reliability study included a subsample of 20 children, 12 with autism, 4 with non-autism developmental disorders, and 4 typically developing children. Interrater reliability was evaluated using weighted kappas; weighted kappas of .60 or greater were considered to indicate acceptable reliability (Cicchetti and Sparrow 1981). A subsample of 20 children was included in these analyses; item ratings (associated with particular activities) on the PL-ADOS yielded weighted kappas between .63 and .95, while weighted kappas for the 31 overall codes ranged from .60 to 1.00.

Clinical Uses

The PL-ADOS was developed as a research measure and was not sold as a widely available clinical measure. It was eventually subsumed by ADOS (including the Module 1 and Toddler Module), which is currently offered for clinical and research use.

Prelinguistic Communication

► Preverbal Communication

Prelinguistic Communication Assessment

Andrea McDuffie

MIND Institute University of California-Davis,
Sacramento, CA, USA

Definition

Both theory and research focused on the early development of spoken language suggest an important causal relationship between prelinguistic or preverbal communication skills and the later emergence of the ability to communicate through spoken language. Thus, assessing the types of preverbal communication acts that a child with autism may use and the situations in which the child is most likely or motivated to communicate has become an important component of comprehensive assessments for young children with autism. Prelinguistic communication refers to a group of behaviors that children use, prior to the emergence of first words, to direct the attention and actions of other people. This category of behaviors is sometimes referred to as “joint attention” or “social communication” with behaviors in this category emerging between 9 and 14 months in typically developing children. Specifically, prelinguistic communication behaviors consist of a combination of gestures (shows, gives, reaches, points), eye gaze, and vocalizations which are used purposefully by children to send a message to a communicative partner. Thus, these behaviors are often referred to as preverbal “intentional communication.” Prelinguistic communication behaviors are used to convey two primary pragmatic functions: to comment on actions and events in the environment and to request an instrumental response from the

communicative partner. These two prelinguistic functions often are termed “initiating joint attention” and “initiating behavioral regulation.” The latter behavior also is referred to as “requesting.” One additional behavior that often is included within the umbrella category of joint attention skills as well as included in assessments measuring prelinguistic communication is termed “attention-following” or “responding to joint attention (RJA).” This behavior refers to the child’s ability to follow into the attentional focus of a communicative partner by responding to cues such as the adult’s point, head turns, and direction of eye gaze. Thus, there are some prelinguistic communication skills which the young child uses to initiate interaction with a social partner and some skills which are used to respond to the partner’s overtures to the child. For children with autism, research has indicated that children’s spontaneous use of prelinguistic communication behaviors are positive predictors of later language outcomes and may present an area of special challenge; that is, children with autism may initiate preverbal communication acts and respond to the adult’s attentional directives at lower rates than their typically developing peers. In addition, children with autism are likely to use a higher proportion of communicative initiations that serve as requests than they are to use initiations which function to comment or share attention with a social partner.

Historical Background

Many research studies conducted since the 1980s have examined and characterized the prelinguistic communication of preschool-aged children with autism. This research has indicated that children with autism most frequently communicate for purposes of behavior regulation and less frequently communicate to share attention and/or affect with another person. Children with autism who have mental ages under 20 months also show deficits in responding to the attentional directives of other people. Response to joint attention at the pretreatment period also has been shown to be a moderator of the relation between the amount of

intervention received by young children with autism and language gains 1 year later for a group of preschool-aged children with autism. Indeed, a deficit in joint attention is considered by many to be a core feature of ASD. Because the ability to initiate and respond to joint attention precedes the emergence of single-word spoken language in typical development, a deficit in joint attention may be considered a core impairment for young children with autism. In addition to characterizing deficits in social communication for young children with autism, other studies have detected robust associations between early prelinguistic communication behaviors and later language for these children. Theoretically, deficits in prelinguistic communication skills may impact language learning in several ways. One theory posits that prelinguistic initiations are foundational because they represent the child's motivation to engage in the kinds of shared interactions with social partners that support the development of socially transmitted skills. Once children develop expertise in initiating to social partners prelinguistically, they need only map spoken words onto the communicative functions they already possess. Another theory suggests that children who direct prelinguistic initiations will elicit language facilitating verbal input from responsive social partners, thus supporting language growth. Finally, theory suggests that children who are able to respond to the attentional directives of others will be more successful in learning language incidentally from the interactions of those around them and less likely to require explicit instruction to learn to speak. All of these theoretical approaches provide a rationale for understanding the emergence of prelinguistic communication skills in young children with autism and targeting these skills in interventions aimed at increasing early language development.

Current Knowledge

The background of research focusing on prelinguistic communication behaviors highlights the importance of assessing prelinguistic communication skills whether for diagnostic or

intervention purposes. To this end, several instruments have been constructed to provide this type of information. The most common method of assessing prelinguistic communication skills is by collecting a sample of these behaviors during an interaction with an examiner. The Early Social Communication Scales (ESCS) and the Communication and Symbolic Behavior Scales (CSBS) are two such instruments including activities that press for initiating joint attention, behavior regulation, and responding joint attention. Module 1 of the Autism Diagnostic Observation Schedule (ADOS) also includes activities designed to elicit prelinguistic communication skills (such as initiating joint attention, reaching, giving, and attention-following). Module 2 of the ADOS includes activities designed to sample attention-following as well as conventional, instrumental, and informational gestures that are used communicatively. In addition to tests which sample prelinguistic skills in an interactive format, parent report also is used to measure these behaviors; the words and gestures subscale of the MacArthur-Bates Communicative Development Inventory includes a section that queries the child's use of communicative gestures. Prelinguistic communication skills also have been included in measures developed for early autism screening. The Modified Checklist for Autism in Toddlers (MCHAT), for example, has an item querying the parent as to whether the child ever points or shows items to them or if the child can respond to the parent's point. The Screening Test for Autism in Two-Year-Olds (STAT) includes items that assess the child's ability to request using eye gaze and vocalization, and to direct attention.

Future Directions

Careful and accurate assessment of the prelinguistic communication skills of young children with autism will contribute to a more nuanced characterization of trajectories of development for these children. In addition, future studies should continue to examine whether interventions targeting early prelinguistic communication skills can improve spoken language outcomes for

children with autism relative to interventions that exclusively target spoken language goals. Finally, assessment of early prelinguistic communication skills may be informative to studies examining aptitude by treatment interactions. It may be that children with different profiles of prelinguistic communication skills would differentially benefit from different intervention approaches.

Premack Principle

Erin E. Barton

University of Colorado Denver, Denver, CO, USA

Synonyms

[Grandma's rule](#)

Definition

The Premack principle is a principle of reinforcement which states that an opportunity to engage in more probable behaviors (or activities) will reinforce less probable behaviors (or activities). For

example, if a child enjoys playing computer games (more probable) and avoids completing math problems (less probable), we might allow her to play the computer after (contingent upon) completing 15 math problems. Prior to the introduction of the Premack principle, systems of reinforcement were viewed as the contingency between a stimulus and behavior. The Premack principle expanded the existing reinforcement contingency of stimulus behavior to include contingencies between two behaviors. This principle is often referred to as “grandma’s rule” because grandmothers (or any caregivers) often apply this principle: “you have to eat your vegetables (less probable) before you can have dessert (more probable)” or “you have to clean your room (less probable) before you can go outside and play (more probable).” In these example, the highly preferred (or probable) activity is used as reinforcement for the less preferred (or probable) activity. David Premack demonstrated this principle with Cebus monkeys and humans, including young children. For example, Premack and his colleagues demonstrated the power of the Premack principle by showing high-probability activities (i.e., playing pinball or eating candy) can be effective reinforcement for low-probability activities, but only if the child prefers the high-probability activity. In this study, highly preferred activities were effective as reinforcers for less preferred behaviors. This study also highlighted the concept that reinforcers are relative and defined in relation to the behaviors they reinforce. For example, eating candy functioned as reinforcement for playing pinball only for children who preferred eating candy to pinball. Conversely, playing pinball functioned as reinforcement for eating only for children who preferred pinball to candy.

Prenatal Diagnosis of Autism

Shoshana Zhang

Yale University, New Haven, CT, USA

Definition

The prenatal diagnosis of autism involves the potential identification of autism spectrum disorder (ASD) symptoms and/or characteristics during pregnancy and before birth (in utero).

Historical Background

Autism spectrum disorder (ASD) is a spectrum or continuum of complex, neuropsychiatric disorders incorporating autistic disorder, Asperger’s disorder, childhood disintegrative disorder, and pervasive developmental disorder (Med 2013). It was first clinically described by the psychiatrist Leo Kanner and pediatrician Has Asperger in the 1940s (Baron-Cohen 2015; Kanner 1943). Initially, geneticists were highly skeptical about a hereditary role in ASD etiology (Newschaffer et al. 2002). However, by the 1980s, there were strong empirical suggestions that ASD was indeed heritable (Newschaffer et al. 2002). ASD can unfortunately affect and hinder an individual’s social, cognitive, and communicative functioning and abilities (Med 2013). Aggression is often understood and noted as the most common problem among ASD individuals; in a 2011 study, Kanne and Mazurek reported that in a sample of 1,380 children and adolescents, 68% and 49% were reported by parents to have displayed aggression to a caregiver and non-caregiver, respectively (Kanne and Mazurek 2011). Thus, ASD has a large impact on the general population.

In a study examining ASD prevalence using 2016 data, Maenner et al. showed that the prevalence of ASD among 11 Autism and Developmental Disabilities Monitoring Networks (ADDMN) was 1 in 54 children aged 8 years old, with prevalence varying by the ADDMN site and state (Maenner 2020). ASD was also 4.3 times more prevalent among boys than girls but varied in prevalence across communities and socio-demographic groups (Maenner 2020). There is also evidence that this male predominance in ASD is partly due to the presence of protective factors reducing the risk of ASD in females (Jeste and Geschwind 2014). These varying aspects of ASD have further pushed for ASD research.

The prevalence of ASD has led to extensive research interests in the biological basis and genetic risk factors of ASD and in understanding the risk genes that facilitate ASD pathways and phenotypes (Jeste and Geschwind 2014). ASD has been shown to have a genetic heterogeneity and strong genetic component, in which rare genetic mutations play roles (Jeste and Geschwind 2014). Since the median age at earliest ASD diagnosis was 51 months or just over 4 years old for 2016, it would be interesting to consider if an earlier median diagnosis is plausible and beneficial (Maenner 2020). Shafali and Geschwind pointed out in a 2014 *Nature Reviews Neurology* review that genetic testing using chromosomal microarray analysis, a clinical diagnostic tool for detecting microdeletions or duplications related to neurodevelopmental and congenital disorders, is “warranted and clinically indicated for all suspected cases of ASD” (Batzir et al. 2015; Jeste and Geschwind 2014). This entry explores the hypothesis that there is a possibility for prenatally testing of ASD risk factors or ASD in utero.

Current Knowledge

Literature Review

ASD, Genetics, and Fetal Development

Researchers have been exploring the risk factors involved with and potential causes for ASD. During the later 1900s, researchers conducted many studies, including twin and family studies, which

suggested a large genetic component to ASD (Anderson et al. 2007). Studies have also pointed out an apparent polygenetic and heterogenetic nature to ASD and an unclear environmental influence on expression (Anderson et al. 2007). As Anderson et al. wrote in 2007, early disorder-associated phenotypes could help in identifying candidate genes, early screening or risk assessment for ASD (Anderson et al. 2007). Since this is a promising avenue for ASD research, many researchers have examined different genetically and biologically based causes for and molecular pathways implicated in ASD.

Researchers have noted several heritable and nonheritable risk factors for ASDs. Some hypotheses point to the following: postnatal changes in head size, brain volume anomalies, neuroanatomic defects (specifically in the amygdala), serotonergic system differences, immune system irregularities, and distinctive neuropeptides or neurotrophins in both ASD groups that could serve as detectable biomarkers (Newschaffer et al. 2002). There has also been suggestions that these anomalies are prenatal in origin, and with this knowledge and other studies, researchers believe that the “neuropathologic process underlying ASD begins in utero” (Newschaffer et al. 2002). In 2014, Stoner et al. found focal disruption of cortical laminar architecture in cortex regions of young children with autism, supporting a possible dysregulation of layer formation and neuronal differential during prenatal development (Stoner et al. 2014). Further work will help to verify these conclusions.

The Placenta and ASD

A study by Anderson et al. in 2007 found that placental trophoblast inclusions are associated with ASD. However, further research was needed to replicate the findings and determine if there was any utility in using these findings as a measure in the early detection of ASD (Anderson et al. 2007). In a more recent study also on the topic of placental gross shape, Park et al. compared placental shape features in a sample of younger siblings of ASD children (a high ASD risk group) and a sample of low-risk peers (Park et al. 2018). They found that in the siblings of ASD children group, there were moderately higher placental thickness

measurements and rounder, more regular in perimeter placentas (Park et al. 2018). These differences did persist for both males and females but were more pronounced in females (Park et al. 2018). The siblings of ASD children group also had reduced placental shape variability (Park et al. 2018). However, the researchers noted their study's limitations stating that future work was still needed to explore whether these placental morphological differences are actually associated with an ASD phenotype (Park et al. 2018).

T Cells and ASD

It has also been hypothesized that alterations in the mother's immune system, like a viral infection during pregnancy, during early periods of fetal neurodevelopment may play a role in ASD. In 2016, Choi et al. reported that the maternal interleukin-17a, the predominant T-helper 17 cell cytokine, pathway promotes autism-like phenotypes in murine offspring (Choi et al. 2016). Interleukin-17a administration to the fetal brain in mice promoted abnormal cortical development and ASD-like behavioral phenotypes (Choi et al. 2016). In pregnant mouse dams, Choi et al. showed that interleukin-17a-blocking antibody therapeutic treatment ameliorated maternal immune activation-associated behavioral abnormalities (Choi et al. 2016). The researchers proposed that therapeutic targeting of T-helper 17 cells in susceptible pregnant mothers could reduce the likelihood of having children with inflammation-induced ASD-like phenotypes (Choi et al. 2016).

Maternal Immune Response and ASD

Other studies have noted that although genetic factors are important for ASD, prenatal maternal immune system responses could also be associated with ASD pathogenesis. In 2009, Zimmerman et al. looked at maternal anti-brain antibodies in autism and identified specific serum antibodies that recognize prenatally expressed brain antigens in the mothers of autistic children (Zimmerman et al. 2007). They suggested that these autoantibodies, antibodies that are capable of binding to self-antigens and serving as disease markers, could transfer across the placenta to alter

fetal brain development (Zimmerman et al. 2007). They concluded that there were distinctive patterns of antibody reactivity to fetal brain in mothers and children, which could be relevant to autism pathogenesis (Zimmerman et al. 2007).

Future Directions

Detecting ASD In Utero

Although previous research efforts have shown that autism is detectable even in infancy, the question that still remains is whether or not prenatal ASD testing is plausible. In 2014, Deborah Brauser wrote an article on WedMD.com stating that in a small study looking at ultrasound scans from 40 children eventually diagnosed with ASD and 120 healthy children, children who eventually developed ASD had larger head and abdominal sizes at 20 weeks in utero than healthy children (Brauser 2014). The lead researcher Lois Salter of the University of Edinburgh had presented these preliminary, not peer-reviewed findings at the 2014 International Congress of the Royal College of Psychiatrists meeting (Brauser 2014). Salter claimed that "something about autism" was occurring at that 20-week mark, and that if further exploration is possible, this finding could "help with diagnosing [ASD] earlier and treating [ASD] earlier" (Brauser 2014). However, the study or its data could not be found online as of April 9, 2020.

There is currently no conclusive test that can predict the probability that pregnant mothers will have a child that will be diagnosed with ASD (Hollowood et al. 2018). However, Hollowood et al. showed in 2018 that among high-risk mothers, mothers who previously had a child with ASD and thus had an elevated risk of having another child with ASD, it was not possible to predict an autism pregnancy outcome (Hollowood et al. 2018). Based on the measurements, Hollowood et al. concluded that it was not possible to "determine during a pregnancy if a child will be diagnosed with ASD by age 3" despite the differences in folate-dependent transmethylation and transsulfuration metabolites being indicative of a mother's risk level for having a child with ASD (Hollowood et al. 2018).

There may be more promising avenues of research for a tool or methodology of detecting ASD in utero or at least at a time point earlier than the current standard for diagnosis. Researches in 2018 hypothesized that a saliva-based poly-“omic” RNA panel could distinguish children with ASD from children with neurotypical and non-ASD developmental delay (Hicks et al. 2018). Hicks et al. concluded that this salivary poly-omic RNA measurement method could be an accurate and non-invasive approach to improve referral specificity for ASD or provide objective support with an ASD diagnosis (Hicks et al. 2018).

Ethical Concerns

While researching this topic, it was clear that earlier diagnostics for ASD could be beneficial for both the mother and child, but the thought of prenatally testing for ASD also brought up ethical concerns. What would and should the pregnant mother do if she knew that she had a high risk of having a child who would develop ASD? Would it engage conversations on abortion or genetic editing using CRISPR-Cas9 for “designer babies” without a high risk for ASD? Would the family then tell their child at a young age that they have ASD and would doing so be beneficial for the family and/or the child?

During a guest genetics lecture by a Yale School of Medicine pediatrician and physician-scientist who studies ASD, on March 24, 2020, the doctor was asked about prenatal screening for ASD. They responded that prenatal, genetic testing is a standard form of care (e.g., Down syndrome and fragile X syndrome), so one can imagine that 1 day physicians could run potentially ASD screens for mothers with reliable risk factors and look for positive results. However, they posed that the question then becomes what does the provider, mother, and/or family do with that sensitive information. ASD, like previously mentioned, is a complex neuropsychiatric disorder, and there is no conclusive evidence that a particular gene “causes” autism. The doctor concluded that although it is controversial to predict ASD based on a gene panel, maybe in the future researchers will be more definitive when looking for mutations related to ASD.

Concluding Remarks

It seems too early to tell if a prenatal test for ASD or ASD testing in utero in general is possible. Although the prospect of such a technique is promising and scientifically interesting with real medical applications, one cannot neglect the ethical concerns and bioethical dilemmas that may be raised. More research is needed to establish conclusive genes or biological anomalies that are early, detectable hallmarks of or markers for ASD.

Preschools are mandated to provide free and appropriate educational programming to children with autism. The communication, social/emotional, and cognitive delays that children with autism often display qualify them to receive a range of services under Parts B and C of the Individuals with Disabilities Education Act (Stahmer and Mandell 2007). Parts C and B of

IDEA require states to provide individualized educational programming to children with disabilities (P.L. 108–446, 2004).

A large number of children with autism attend preschool (Department of Education 2006). In 2006, 35,081 preschoolers with autism received individualized educational programming as a result of their autism diagnosis (Department of Education 2006). Most studies report the number of preschoolers served under the autism label is increasing (Bitterman et al. 2008; Department of Education 2006; White et al. 2007).

Standard preschool practices do not currently seem to optimize the development of preschoolers with autism. Many public preschool teachers report that they do not use “scientifically based” or “evidence-based” strategies (Hess et al. 2008; Stahmer et al. 2005; Stahmer et al. 2007). In one study, less than 10% of the strategies public school teachers reported using were scientifically based and 33% of the strategies had a limited evidence base (Hess et al. 2008). The most common strategies that public preschool teachers reported using were floor time, incidental teaching, visual schedules, social stories, sensory integration, and music therapy. In a similar study, approximately 33% of the strategies that preschool teachers reported using were evidence based and teachers acknowledged that there was no research regarding 30% of the strategies they used (Stahmer et al. 2005). The most common intervention techniques were applied behavior analysis, floor time, occupational therapy, PECS, sign language, and social stories.

Preschoolers with autism exhibit characteristic impairments in communication and social skills (DSM-IV 1994). Currently, most preschools do not effectively improve upon the communication and social skill deficits of children with autism. Teachers infrequently use validated strategies to promote the social communication of young children with autism. For example, despite that research suggests it is important to respond to the communicative gestures of children with autism (Smith et al. 1988), preschool teachers tend to respond to very few communicative gestures of young children with autism (Keen et al. 2005; Wong 2006). When teachers do respond to the communication of children with autism, they

typically do not respond in ways that will facilitate better social communication (McCathren 2000). Likewise, although children with autism benefit when adults use joint attention gestures (Smith et al. 1988), teachers of children with autism use few joint attention and behavior regulation gestures (McCathren 2000). Similarly, teachers of children with autism typically prompt for verbal communication much less than is recommended for children who are typically developing or developmentally delayed (Chiang 2009).

Preschool teachers also spend relatively little time engaging in pretend play with children who are typically developing or who have autism (Kontos and Keyes 1999; Wong 2006). This reality is troubling because pretend play is believed to be an important component of early childhood autism interventions targeting communication and social skill (Charman et al. 2003). Some contend that preschool programs devote less attention to pretend play than previous decades for several reasons: teachers failing to recognize the importance of play, teachers not knowing how to teach play, class schedules that do not allow time to properly play, as well as greater emphasis upon academic standards (Malone and Langone 1999).

There have been some peer-reviewed publications of preschool interventions targeting the communication and social skill deficits of young children with autism. Most of the experimental interventions report significant improvement in child performance, though they are overwhelmingly plagued by methodological weaknesses. Common shortcomings include a weak experimental design, lack of detail regarding participants, too little information regarding the subjects and experimental treatment, failure to include independent coders and/or assessors, as well as improper data analyses. Future work must correct these weaknesses so that public preschools become a context where the communication and social skill deficits of young children with autism can be effectively improved.

Definition

Preschool curriculum provides a guide for *what* to teach young children. Usually organized in a developmental sequence, preschool curriculum traditionally refers to the content of what is taught, which can be comprehensive or focus on specific domains. For children with autism, preschool curriculum typically addresses the following target areas: social-communication skills, problem behaviors, sensory and motor skills, pre-academic skills, and adaptive behavior.

Beyond content, preschool curriculum can also include assessment procedures for setting goals and monitoring progress as well as intervention strategies for guiding *how* to teach young children. Practitioners working with young children

with autism can follow a published preschool curriculum or draw from multiple sources to design a more specific curriculum.

Curriculum Design/Selection

Autism is a spectrum disorder in which there is a great deal of heterogeneity. Therefore, curricular decisions must be individualized for young children with autism as well as their families. Following is a brief summary of issues to consider when selecting and adapting preschool curriculum for young children with autism.

Target Early Core Characteristics of Autism

In designing or selecting curriculum for a young child with autism, the child's skills must be considered in relation to the early core characteristics of autism: social-communication and repetitive behavior or restricted interests. Specifically, young children with autism have difficulty with engagement, joint attention, and symbolic play, all of which affect learning and development (Kasari et al. 2008).

Engagement. If a child is not purposefully engaged in activities or interactions, the opportunities for learning are dramatically reduced (Iovannone et al. 2003). In addition to active engagement, an important curricular goal for young children with autism is to increase the amount of time children with autism are *jointly* engaged in activities while shifting their attention between the activity and their interaction partners (Kasari et al. 2010).

Joint Attention. Joint attention refers to the ability to shift attention between objects or events and other people in order to share interest and plays an important role in language development (Loveland and Landry 1986). Specific skills include pointing and showing with coordinated joint looks which involves a child looking at a target object, then making eye contact with another person, and then back to the target object. For example, to share interest about a toy, a child may be looking at the toy, then glance up to look at the caregiver, and then look back at the toy. Compared to typically developing children and children with intellectual disabilities matched on mental age, children with autism have specific

deficits in initiating and responding to joint attention (Mundy et al. 1986). Children with autism are more likely to use pointing and attention skills to regulate others' behaviors rather than to share interest.

Symbolic Play. Symbolic or pretend play involves the representation of objects as something else. Children typically progress developmentally from playing with toys functionally, such as in constructive and manipulative play, to playing with toys symbolically (Lifter et al. 1993). However, in comparison to typically developing peers, children with autism at the same mental ages have significant delays in the development of symbolic play (Jarrold et al. 1993). Children with autism tend to manipulate toys or objects in a rigid or stereotyped manner rather than spontaneously initiate creative symbolic play activities (Libby et al. 1998).

Functionality

In addition to targeting the early core characteristics of autism, a well-designed preschool curriculum for young children with autism must also include content that serves a functional purpose for the child (Schertz et al. 2010). It is critical to focus on skills that are required for the child to be functional in a less restrictive or natural environment. For example, reducing aggressive behaviors and tantrums will allow the child to engage socially with others and, thus, may serve a more functional purpose than being able to color a picture within the lines.

Generalizability. A key concept regarding functionality is generalizability. Generalizing refers to extending what has been learned in one context to new and different contexts. Care must be taken so that children with autism can perform particular acts beyond the specific setting and manner they were taught. For curricular goals to be truly functional, they should have meaning in the child's everyday activities. Therefore, preschool curriculum must extend beyond interactions with only one person, setting, and/or activity. Furthermore, because generalizing may be particularly difficult for young children with autism, learning may be more meaningful and effective when specific skills are taught in natural settings.

Developmentally Appropriate

Preschool curricula are usually organized in a developmental sequence beginning with more basic skills and leading to more complex skills within a domain. In deciding where to begin within a curriculum, the individual goals or targets for the young child with autism must be developmentally appropriate, meaning that they are just above the child's level (zone of proximal development; Vygotsky 1978). Content that is too easy may not be stimulating enough while content that is too difficult may lead to frustration. Therefore, it is important to target a child's emerging skills and then guide or scaffold the child to master that skill.

Socially and Culturally Relevant

Finally, preschool curriculum needs to be socially and culturally relevant to children with autism, their families, and their communities. In addition to considering developmental level, the curriculum and materials must also reflect what is socially appropriate for the child's age (age appropriateness; Schertz et al. 2010). Although children with autism often show an uneven pattern of development, it is important to note the general characteristics of typically developing preschool-aged children in the community. While strengths and special interests should be nurtured and integrated within a child's curriculum, especially to help increase skills in areas of weakness, special attention must be paid to social norms in order to better facilitate independent functioning in natural environments. Indeed, in preschool, play is the natural setting for learning and interacting with others. The involvement of a professional familiar with typically developing preschoolers (e.g., preschool teacher) is essential to validating social relevance.

Even more critical is the inclusion of the family in determining social and cultural relevance. Input from the family will determine the curricular goals that are most valued and should be prioritized. It is the responsibility of the professionals to provide information to the families to help empower them to make informed decisions and make their preferences known.

Curriculum materials that reflect children's cultural and ethnic backgrounds will also promote generalization and positive ethnic identity (Hall 2009).

Assessment

Many of the issues identified previously in designing and/or selecting preschool curriculum require extensive knowledge of the individual child with autism, thereby requiring assessments in order to appropriately individualize preschool curriculum. Assessment is a process of collecting information in order to make decisions. In this case, assessment of a child is needed to provide data for making decisions about what to teach the child with autism. This process is important initially for deciding upon the curriculum and then adapting the curriculum as appropriate in order to monitor progress on an ongoing process (Schertz et al. 2010). The most helpful type of assessments for curricular decisions is usually curriculum-based assessments.

Curriculum-based assessments (also known as criterion-referenced tests) include a list of skills and behaviors (usually linked to a specific curriculum) that can be measured and recorded. To be useful, the assessment measure must be sensitive to changes. Performance on these objectives is scored which provides information on the child's mastered and emerging skills. In this way, a developmentally appropriate curriculum can be specified for the individual child with autism. The skills are then measured at regular intervals in order to track progress with objectives. This monitoring provides data to determine if curricular content and sequence and/or intervention strategies need to be modified. Most published preschool curriculum guides will include a curriculum-based assessment that parallels the curriculum content.

Intervention

Although the strict definition of preschool curriculum only refers to the *content* of what is taught, many published curricula today often include intervention strategies that guide *how* to teach the specified skills and behaviors. Intervention guidelines may range from providing a general approach or practices to offering specific activities and materials for facilitating the target skills. Although interventions within a curriculum may be based off of different theoretical models, it is imperative to acknowledge the same key issues for making curricular decisions: targeting the early core characteristics of autism and ensuring

functionality, developmental appropriateness, and social and cultural relevance.

Commonly Used Preschool Curricula

Published preschool curricula that can be used for young children with autism include those designed for typically developing children, children with special needs, and specifically for autism. Following is a brief description of commonly used published curricula for preschoolers with autism. This list is presented in alphabetical order and is not intended to be comprehensive:

- *Assessment, Evaluation, Programming System for Infants and Children, Second Edition* (AEPS; Bricker 2002). The AEPS is a 4-volume set of assessment and curriculum materials for use with young children at birth through age 6. Assessment and curriculum items are organized into six key domains: social, social-communication, fine motor, gross motor, adaptive, and cognitive.
- *Assessment of Basic Language and Learning Skills-Revised* (ABLLS-R; Partington 2006). The ABLLS-R includes a curriculum-based assessment, curriculum guide, and skills tracking system for use with children with autism or other developmental disabilities between the ages of 3 and 9. With a particular emphasis on language skills, the ABLLS-R also includes information for developing an Individualized Education Program (IEP) for the child.
- *The Carolina Curriculum for Preschoolers with Special Needs, Second Edition* (CCPSN; Johnson-Martin et al. 2004). The CCPSN is designed for assessing and teaching children with mild to severe special needs from 2 to 5 years' developmental age. Organized into 22 teaching sequences spanning five developmental domains, each curricular item includes suggested teaching procedures, materials, routine integration strategies, and sensorimotor adaptations.
- *The Creative Curriculum for Preschool, Fourth Edition* (Dodge et al. 2006) provides suggestions for arranging educational environment so that goals and objectives can be embedded within a daily schedule while balancing both teacher-directed and child-

initiated learning. The Creative Curriculum includes an assessment instrument as well as specific intervention strategies.

- *Hawaii Early Learning Profile 3–6* (HELP 3–6; Teaford et al. 2010). HELP 3–6 is a family-centered, comprehensive, and developmentally sequenced curriculum-based assessment that also offers play-based activities and intervention strategies for the behaviors and skills. Covering 622 skills in six domains, HELP 3–6 is designed for typically developing children as well as children who may have developmental delays.
- *More Than Words* (Sussman 1999). Drawn from *More Than Words – The Hanen Program for Parents of Children with Autism Spectrum Disorder*, this resource book was developed by speech-language pathologists and provides practical, research-based strategies using everyday activities and includes charts and checklists. Designed for parents, *More Than Words* specifically focuses on promoting communication and social skills in children with autism spectrum disorder.
- *The SCERTS Model: A Comprehensive Educational Approach for Children with Autism Spectrum Disorders* (Prizant et al. 2006). The SCERTS model stands for social-communication, emotional regulation, and transactional supports to improve the communication and social-emotional abilities in individuals with autism spectrum disorders. This resource includes two volumes: Volume I targets assessment and volume 2 targets program planning and intervention.
- *Selecting Teaching Programs* (Taylor and McDonough 1996, chapter in Maurice, Green, & Luce (Eds.), *Behavioral intervention for young children with autism: A manual for parents and professionals*). This chapter provides detailed teaching programs and a simple curriculum guide for implementing a behavioral program for children with autism.
- *Teaching Individuals with Developmental Delays: Basic Intervention Techniques* (Lovaas 2003). Guided by a behavioral approach and targeted towards the education of individuals with autism, this book provides detailed descriptions of current programs

within the following sections: basic concepts, transition to treatment, early learning concepts, expressive language, strategies for visual learners, and programmatic consideration.

- *A Work in Progress: Behavior Management Strategies and a Curriculum for Intensive Behavioral Treatment of Autism* (Leaf and McEachin 1999). A Work in Progress is a comprehensive and detailed curriculum guide that presents behaviorally based intervention strategies for families and/or professionals working with children with autism.
- *The Ziggurat Model – A Framework for Designing Comprehensive Interventions for Individuals with High-Functioning Autism and Asperger Syndrome* (Aspy and Grossman 2011). The Ziggurat Model provides a process for designing interventions for individuals with autism spectrum disorder. Included in the book is the Underlying Characteristics Checklist for Early Intervention which identifies characteristics associated with autism across multiple domains.

Historical Background

Although Public Law 94–142 gave students with disabilities the right to a free and appropriate public education in 1975, it was not until 1986 when those provisions were extended to preschool-aged children with disabilities (P.L. 99–857). Additionally, while autism was first described in 1943, autism was not added as a distinct federal disability category until 1990 (P.L. 101–476). Paralleling the recognition of autism as a separate category is the rising prevalence of autism. In the 1980s, prevalence rates for autism were estimated to be between 2 and 5 per 10,000. The Centers for Disease Control and Prevention (2009) now report current prevalence rates to be 1 in 110 (Schertz et al. 2010). Furthermore, while symptoms of autism appear before the age of 3, diagnosis often occurred later. However, with the broadening of the autism diagnostic criteria, greater public awareness of autism, and improved screening and diagnostic assessment tools and procedures, the majority of children with autism are diagnosed during the preschool years (Howlin and Moore 1997; Wiggins et al. 2006). In fact, the U.S. Department of Education, Special

Education Programs and Data Analysis System (2007) reported that 35,081 preschoolers received special education services under the autism category in 2006.

Different theoretical models of intervention have guided the development of distinct curriculum for children with autism (Olley 1999). Specific intervention for children with autism began in the 1970s with the structured teaching approach that has now become the TEACCH program and the applied behavioral approach (Schertz et al. 2010). Developmental approaches produced curricula based upon typical developmental sequences of learning (Mirenda and Donnellan 1987), while behavioral approaches tended to target eliminating or reducing interfering behaviors while promoting more positive behaviors. Current preschool curriculum for children with autism tends to provide a more integrated approach and now includes content for each of the major developmental domains. However, specific emphasis may be given to communication, social skills, and reduction of interfering behaviors, consistent with the core symptoms of autism. At this time, there are no national curricular standards for educating young children with autism (Olley 1999).

Rationale or Underlying Theory

Children with autism who participate in preschool programs with curriculum that targets core domains of impairment tend to have improved outcome and prognosis than those who do not. Curriculum provides a guide for systematic intervention. Regardless of intervention approach, the critical factor seems to be providing instruction that is thoughtfully planned and systematically delivered (Schertz et al. 2010). According to Iovannone et al. (2003) "Systematic instruction involves carefully planning for instruction by identifying valid educational goals, carefully, outlining instructional procedures for teaching, implementing the instructional procedures, evaluating the effectiveness of the teaching procedures, and adjusting instruction based on data." (p. 157). Therefore, preschool curriculum plays a critical role in the education of young children with autism in being linked systematically with assessment and intervention.

Treatment Participants

The preschool years are typically defined as ages 3–5. In the United States, local school systems provide education for children with special needs beginning at age 3, while Part C early intervention programs provide services under age 3.

Individuals responsible for preschool curriculum planning will include all members of the instructional or Individualized Educational Planning (IEP) team. This team includes family members and an intervention specialist or teacher as well as other specific service providers such as a speech-language pathologist, occupational therapist, adaptive physical education teacher, physical therapist, and/or school psychologist. A general education teacher can arrange for adaptations and supports needed for access to the general preschool curriculum as well as to promote successful inclusion with typically developing peers. Autism specialists may also be included to help the team design curriculum for young children with autism (Hall 2009).

Efficacy Information

Although research shows that intervention at young ages can improve developmental outcomes and trajectories for children with autism (National Research Council 2001), there is less consensus regarding specific intervention approaches. As a result of this controversy, the importance of curriculum has been overlooked in the literature (Olley 1999). Therefore, at this time, there is no standard curriculum for young children with autism as no single curriculum has been shown to be universally effective.

Overall, because of the focus on intervention and establishing evidence-based practices, little research has been conducted on determining what is important to teach and the sequence in which content should be taught. Reviews of the literature have identified domains of functioning that warrant intervention, strategies often used to target those domains, and a brief description of existing programs (Dawson and Osterling 1997; National Research Council 2001; Odom et al. 2010). Indeed, there have been many well-

designed studies evaluating intervention programs with well-developed curricula but few have evaluated the curriculum guides themselves. Research findings typically address outcomes as a result of the entire treatment package which address both content and intervention strategy, thus making it difficult to determine the specific effects of the curricular component versus the instructional component (Olley 1999).

Future research should look more closely at preschool curriculum to determine the scope and sequence of skills in order to determine the content most critical for young children with autism to learn for promoting later development.

child has receptive or expressive language delay/disorder or combination of both as well as to determine eligibility for early intervention or speech/language services. Item responses are obtained through a combination of direct testing, observation of spontaneous interactions, and through caregiver report. It is comprised of two subscales: auditory comprehension and expressive communication. Areas covered in the receptive and expressive subscales include preverbal skills, language content and structure, integrative language skills (thinking using language), and emergent literacy. Standard scores, percentile ranks, and age equivalents are derived for each subscale as well as an overall total language score. It also provides three supplemental assessments: language sample checklist, articulation screener, and caregiver questionnaire. Criterion scores are derived for the articulation screener for children 2 years 6 months to 7 years 11 months of age.

Historical Background

The Preschool Language Scale was first developed in 1969 as a measure of language development in young children. It was revised several times, and in 1992, the PLS-3 was published using normative data for standard scores and percentile ranks; the PLS-IV appeared in 2002, with a Spanish language version. The PLS-5, published in 2011, is the latest edition, which also includes a Spanish version.

Psychometric Data

From 45 states in the USA, 1,400 children participated in the standardization normative sample, collected in more than 45 states in the United States. The standardization sample matches US Census figures (March 2008 update) for age, sex, geographic region, race/ethnicity, and primary caregiver's education. Norms are reported for 3-month intervals for children from birth to 11 months and 6-month intervals for ages 12 months to 7 years 11 months. Clinical studies include a developmental delay study and three language disorder

Synonyms

PLS-5

Description

The Preschool Language Scale-Fifth Edition (PLS-5) was developed to identify whether a

studies (children with receptive language disorder, expressive language disorder, and both receptive and expressive disorder); case studies include children identified as high risk (environmental risk) and children identified with autism. Multiple reviews for bias were conducted throughout the test development. Nationally recognized experts in assessment and bias issues conducted a thorough review of test items and picture stimuli. An additional sample of African American and Hispanic children was tested to conduct the statistical analysis of bias. Split-half reliabilities range from 0.80 to 0.97. Sensitivity for the total language score is 0.83; specificity is 0.80.

Clinical Uses

It may be administered by a variety of qualified users such as speech-language pathologists, early childhood specialists, and psychologists as well as professionals trained to administer the assessment. Paraprofessionals may also administer the assessment; however, it should be scored and interpreted by experienced professionals. The purpose of the assessment is to identify delays inexpressive and/or receptive language development.

Pressure/Squeeze Machine

Winifred Schultz-Krohn

Department of Occupational Therapy, San José State University, San José, CA, USA

Definition

The squeeze machine, otherwise known as Grandin's Hug Machine, is a device that allows self-administered deep pressure along the sides of the body. This device was developed by Temple Grandin, a woman who has autism, to reduce her level of anxiety and arousal. The machine allows an individual to be positioned prone in the machine with the head supported outside of the machine, which looks like a large box. The box is open on each end with your head and forearms out one end and your lower legs out the other end. The individual is then able to control and grade the amount of pressure using a switch. An investigation using two groups of children, all diagnosed with autism, demonstrated the effectiveness of using Grandin's Hug Machine to decrease the level of arousal measured by galvanic skin response and the level of anxiety measured by the Connors Parent Rating Scale. Children who used Grandin's Hug Machine twice a week for 6 weeks displayed reduction in the level of arousal and reduced anxiety using these measures and when compared to children who were positioned in the Hug Machine but without the availability of receiving the deep pressure.

Presupposition

Megan Lyons
Laboratory of Developmental Communication Disorders, Yale Social and Affective Neurodevelopment of Autism Program, Yale Child Study Center, New Haven, CT, USA

Synonyms

[Theory of mind](#)

Definition

Presupposition is an aspect of pragmatic or social language use. It entails an implicit assumption about the background knowledge relating to an utterance whose truth is taken for granted in discourse. A presupposition must be mutually known or assumed by the speaker and listener for the utterance to be considered appropriate in context.

Example of presupposition includes:

- Jim no longer teaches children with ASD.
 - Presupposition: Jim once taught children with ASD.

Presuppositional knowledge allows speakers to provide the correct amount of information necessary to get their message across to a listener. For example, it is not necessary to say “Jim once taught children with ASD. Jim no longer teaches children with ASD.” The second sentence presupposes the first, so the first does not need to be stated explicitly.

Many individuals with ASD have difficulty with presuppositional knowledge. They may provide too much or too little information because they have difficulty taking into account what their listener can reasonably be expected to know. For example, a speaker with ASD may start a conversation by saying, “WOW is my favorite game,” without determining whether it is reasonable to expect that the listener will know that WOW refers to World of Warcraft. Difficulties in the use of presuppositional knowledge can result in communication breakdowns and affect others’ perceptions of the speaker and their willingness to engage in conversation with him. Presuppositional skills are closely related to the “theory of mind” skills that are thought to be impaired in individuals with ASD.

Pretend Play

- [Play](#)

Pretense

- [Imagination](#)

Prevalence

Lisa Croen

Autism Research Program, Kaiser Permanente
Division of Research, Oakland, CA, USA

Synonyms

[Period prevalence](#); [Point prevalence](#)

Definition

Prevalence is the percent of persons in a population with a certain condition. Prevalence combines both preexisting cases and incident cases together to form a numerator, which is then divided by the total population being studied. Like incidence, prevalence must be calculated for a specified time frame. If that time frame spans a broad range of time (i.e., a year, 10 years, etc.), then prevalence over that time frame is referred to as a “period prevalence.” If the time frame is relatively short, then the prevalence measure is often called “point prevalence.”

An example of when point prevalence would be measured would be visiting a clinic and counting the number of children with and without ASD on that day. Cases of ASD could be children who were diagnosed with ASD on that day, as well as children who had been previously diagnosed. Point prevalence is often compared to a photograph: data are collected all at once (or over a brief time period), and the majority of cases are preexisting cases, as there is little to no time for incident cases to occur. Period prevalence, on the other hand, has a broader time frame for measurement of preexisting and new cases, which may allow more new cases of disease to develop. An example of period prevalence could involve following the children in the prior example for a year. Those who were diagnosed with ASD within that year would be combined with children with prior ASD diagnoses to form a numerator, and the denominator would be the total number of children being followed in the cohort.

Preverbal Communication

Andrea McDuffie

MIND Institute University of California-Davis,
Sacramento, CA, USA

Synonyms

[Early social communication](#); [Prelinguistic communication](#)

Definition

The term “preverbal communication” describes a group of social communication behaviors that are used to send an intentional, or purposeful, message to a communicative partner. Rather than being verbal in form (i.e., composed of words or word combinations), preverbal communication acts consist of some combination of eye gaze, gesture, and/or vocalization. The core feature of a preverbal communication act is that the child purposefully directs this behavior toward a communicative partner. Preverbal communication acts can take the form of conventional gestures such as showing, giving, open-handed reaching, pointing, nodding or shaking the head, and waving. Leading the adult by the hand toward a desired item also is a common preverbal communication strategy observed in children with autism. The most common pragmatic functions of preverbal communication acts are commenting and requesting.

Primacy Effects

Rhea Paul¹ and Deborah Weiss²

¹Department of Speech and Language Pathology, College of Health Professions, Sacred Heart University, Fairfield, CT, USA

²Department of Communication Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[Cognitive bias](#); [Recency effect](#); [Serial position effect](#)

Definition

Primacy effect is the tendency to remember the first few things presented when given a list of items to recall. An individual will also have a tendency to assume that those things presented at the beginning of a list are of greater importance than those presented in the middle or end of the list. The first item or first few items may be transferred to long-term memory by the time of recall, while items at the end of the list are still in short-term memory. This has implications for learning, memorizing information, and making selections.

This effect was first described by Asch (1946) when he requested that participants judge a person based upon a list of descriptive attributes. Two lists, containing identical positive and negative descriptors, were presented. In one instance, the positive descriptors were presented at the beginning of the list, and in the other instance, the negative descriptors were presented at the beginning of the list. Those participants who were presented with the list of positive descriptors first rated the person more highly than those participants who were presented with the list of negative descriptors first.

Primary Sensory Areas

Susan Y. Bookheimer
Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA, USA

Synonyms

[Auditory cortex](#); [Somatosensory cortex](#); [Visual cortex](#)

Definition

Areas of the cerebral cortex that receive the first signals from sensory receptors are called primary sensory areas. These areas are separate for each sensory modality, but the major primary sensory regions are those for vision, hearing, and sensation.

Vision: Primary visual cortex lies in the lingual gyrus of the occipital lobe on both sides of the calcarine sulcus. Histologically termed Brodmann’s area 17, primary visual cortex is organized topographically, such that each part of the cortex represents a specific part of one’s visual field.

Hearing: Primary auditory cortex lies along the upper bank of the temporal lobe in the transverse temporal gyri, also termed Heschl’s gyrus. Histologically, the neurons comprising primary auditory cortex (A1) are labeled Brodmann’s areas 41 and 42. Auditory information from both ears

is processed in both the right and left hemispheres, and the organization is tonotopic: Different areas of cortex respond preferentially to different sound frequencies.

Sensation: The brain region that processes tactile sensations is called primary somatosensory cortex. Located on the postcentral gyrus in the parietal lobe just behind motor cortex in Brodmann’s areas 2, 1, and 3, the “sensory strip” has a topographic representation in the form of a homunculus, with exaggerated representations of sensitive areas such as the hands, lips, tongue, and genitals.

Primate Prosocial Behaviors

Alicia Melis¹ and Felix Warneken²

¹Department of Developmental and Comparative Psychology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

²Department of Psychology, Harvard University, Cambridge, MA, USA

Definition

Cooperation: Umbrella term for social interactions among conspecifics which provide a benefit

to another individual (recipient) or to both the actor and the recipient. Cooperative behaviors thus comprise both altruistic and mutualistic interactions (Melis and Semmann 2010).

Altruistic or investing behaviors: Social behaviors in which only the recipient obtains immediate benefits, and actors' motivation is to intervene toward the recipient's goal or need (Warneken and Melis 2012).

Collaborative behaviors: Mutually beneficial behaviors in which two or more individuals coordinate their actions to produce outcomes from which both individuals benefit immediately, such as obtaining a common resource or producing an effect that one individual would not be able to produce on her or his own (Warneken and Melis 2012).

Historical Background

Human cooperative behavior exceeds that of all other species with regard to the scale and range of cooperative activities. Specifically, how did humans become so collaborative and skilled at maintaining cooperation in large groups of unrelated individuals? Which cooperation skills do we share with other species and which are unique to humans? Comparative studies of humans and chimpanzees as well as bonobos as our two closest living primate relatives can help us to identify those cooperative skills that already characterized the last common ancestor and those derived skills unique to the human lineage.

For a long time, natural observations have accumulated evidence that nonhuman primates behave cooperatively across many different contexts such as food sharing, allo-maternal care, territorial and predator defense, grooming, coalitionary support and aggression, and cooperative hunting (Kappeler and van Schaik 2006). However, it is only in the last decade that experimental studies have started to investigate the psychological mechanisms that underlie these cooperative behaviors.

Here, we will focus mainly on the experimental work conducted with chimpanzees and bonobos, since they are our closest living evolutionary

relatives, and a significant body of empirical evidence has accumulated in recent years, occasionally even allowing direct comparisons between humans and mainly chimpanzees.

Current Knowledge

We will first summarize the available evidence for altruistic behaviors in chimpanzees, focusing on both food-sharing behavior and instrumental helping. Altruistic behaviors are particularly interesting from a motivational point of view, since individuals act on behalf of others, without obtaining any immediate benefit from it, and potentially incurring serious costs. Although altruistic behaviors in humans are often maintained via reciprocation, there is no good evidence suggesting that nonhuman primates understand the long-term benefits of alternating favors or that they engage in altruistic behavior motivated by the prospect of a future selfish reward. From a cognitive point of view, altruistic behaviors require that individuals attend to and can infer what others need or desire.

Second, we will summarize the current knowledge on chimpanzees' and bonobos' ability to collaboratively solve problems. Collaborative behaviors are from a motivational perspective easier to explain, since individuals should be generally selfishly motivated to collaborate (unless they can free-ride profiting from the work of others without making any effort themselves, as in large-scale forms of cooperation). The challenge of collaborative behaviors is instead cognitive, since individuals need to understand how the different roles are interrelated with each other and how best to coordinate their behavior to that of the partner(s) in order to achieve the joint goal.

Altruistic Behaviors in Chimpanzees

Natural observations show that chimpanzees occasionally act on behalf of others. Interestingly, the beneficiaries of these helping acts are not just the helper's relatives, as is mostly the case among other nonhuman primates, but also nonrelatives (Langergraber et al. 2007). Several anecdotal

reports have shown that chimpanzees occasionally assist others, as is the case of the chimpanzee who rescued another nonrelated female from drowning in the moat of their enclosure (Fouts and Mills 1997) or the reported cases of adoptions by chimpanzee males (Boesch et al. 2010). In addition, there is evidence that chimpanzees regularly engage in behaviors such as food sharing, coalitionary support, and consolation (e.g., Boesch and Boesch-Achermann 2000; de Waal and Aureli 1996; Muller and Mitani 2005). However, the difficulty with many of these observations is that it is not always possible to rule out a selfish motivation behind actors' actions, since often these behaviors also lead to immediate benefits for the actors. For example, food-sharing behavior has also been explained by the "harassment" or "sharing-under-pressure" hypothesis (Gilby 2006). According to this hypothesis, chimpanzees share meat after group hunts not out of a concern for the welfare of others and to fulfill the others' needs and desires, but they share under duress. That is, beggars' insistent behavior interferes with the possessor's ability to feed and/or increases the risk that the possessor will get injured if beggars become increasingly aggressive. Therefore, individuals are better off if they give a piece to the beggars and can then continue feeding alone.

Experimental studies that present chimpanzees with situations in which subjects can potentially share resources and help others – at the same time that helpers' selfish gains can be ruled out – are starting to reveal chimpanzees' ability and propensity to act on behalf of others, as well as the circumstances under which these tendencies are expressed.

Food Sharing in Chimpanzees

Food sharing is an important aspect in the social life of chimpanzees. It occurs regularly and more often than among other nonhuman primate species (with the exception of the Callitrichidae, one family of New World monkeys). Characteristic of chimpanzee food sharing (in particular meat sharing after hunting monkeys or other mammals) is that it occurs not only among mother-offspring

dyads but also between unrelated individuals of different age and sex classes. Typically, chimpanzee food sharing is mostly "passive": food possessors tolerate beggars taking food from them. In general, very few instances of active sharing are observed, not even among mother-offspring pairs (Boesch and Boesch 1989; Ueno and Matsuzawa 2004). This suggests the possibility that food donors share to avoid being harassed by the beggars (Gilby 2006) and are not truly motivated to share food with others.

Several experimental studies investigating chimpanzees' propensity to provide food rewards to conspecifics have come to the same conclusion. The main method employed in these studies was to let chimpanzees choose between an option that would deliver a food piece to themselves and another food piece to a conspecific (mutualistic option) or an option that would deliver food only to themselves (selfish option). In all these studies chimpanzees chose randomly between the two options, even if the mutualistic choice would come at no cost to themselves. As chimpanzees did not deliver food to their partner, the general conclusion from these studies was that chimpanzees are indifferent to the welfare of their partners (Jensen et al. 2006; Silk et al. 2005; Vonk et al. 2008; Yamamoto and Tanaka 2010).

However, in a recent study chimpanzees did actively provide food to others (Melis et al. 2011). In this experimental setup, rather than choosing between a mutualistic and a selfish outcome, chimpanzees could help a conspecific obtain food that was out of reach by letting it slide down a ramp toward the recipient (see Fig. 1). The potential helper could never obtain the reward herself. Results showed that subjects released the food when the partner was actively communicating his goal by trying to get at the food or getting the helper's attention. This suggests that as long as partners actively signal their goals and/or desires, and the altruistic act does not interfere with the actor's selfish goals, there are situations in which chimpanzees are willing to provide food to others.

Importantly, active provision of food seems to occur only if the opportunity to monopolize

Primate Prosocial Behaviors,

Fig. 1 Experimental setup and main results of Melis et al. (2011): (a) subjects can help a conspecific by releasing a peg that stops a bag with food from sliding down the ramp; (b) subjects released the bag significantly more often when the recipient communicated his goal (“active”) than when he was passive or was not in the room

resources is removed. These results thus do not challenge the conclusion that our nearest living primate relatives are not particularly inclined to actively share resources with others when they could have it for themselves (e.g., Warneken and Tomasello 2009).

Instrumental Helping in Chimpanzees

A series of recent experimental studies have shown that under certain circumstances chimpanzees act on others' behalf assisting them to achieve their goals. This has been called “instrumental” or “targeted” helping (Warneken and Tomasello 2006). Warneken and Tomasello (2006) found that human-raised chimpanzees helped their human caregiver by handing her objects she was unsuccessfully reaching for even in the absence of an external reward. Moreover, a further study by Warneken et al. 2007, showed that a group of semi-free ranging chimpanzees also helped by handing the out-of-reach object to a human who had not interacted with them before

the experiment. The chimpanzees did so irrespective of being rewarded and when they had to actively climb toward the out-of-reach object (Warneken et al. 2007, Experiment 2). This shows that chimpanzees are willing and able to help human strangers obtain objects, even when helping is made effortful and they receive no immediate benefit for themselves.

However, the most ecologically valid question is whether chimpanzees would help other chimpanzees. This has now been demonstrated in three additional experimental paradigms. First, Warneken et al. (2007), Experiment 3, Melis et al. 2008) created a novel situation in which chimpanzees could help an unrelated conspecific to enter a room with food by releasing a chain that was blocking the door. Chimpanzees released the chain significantly more often when the recipient was unsuccessfully trying to enter the room, than in control conditions in which releasing the chain would either not help the recipient (because he was trying to go somewhere else) or no recipient

was present. Probably, recipients' unsuccessful attempts to open the door provided the subjects with the necessary cues to help them detect the recipients' goal.

In a second paradigm by Yamamoto et al. (2009), chimpanzees altruistically helped a conspecific partner by transferring a tool the other needed to access food. This occurred almost exclusively in situations preceded by recipients' communicative cues, such as reaching for the tool (e.g., arm poking) or getting the potential helper's attention (e.g., clapping hands, looking at helper). Chimpanzees virtually never handed over the tool proactively without such a cue, providing further evidence for the notion that recipient cues are critical to elicit helping.

In a third paradigm (Melis et al. 2011), the subject could release a bag with a reward so that it would slide down a ramp toward a recipient. Chimpanzees released the bag more often when the recipient was actively trying to access the reward (e.g., by pulling a rope attached to the bag) or communicate toward the potential helper than when the recipient remained passive. Thus, the main factor predicting helping was again the communicative cues (intentional or not) of the recipient.

This series of studies show that under certain circumstances, chimpanzees act on behalf of others by helping them to achieve their goals, even if it involves accessing food. However, as in the case of food sharing, they seem to engage in instrumental helping in a (re)active rather than proactive way (Melis et al. 2010; Warneken and Tomasello 2008). That is, in all these cases helping was preceded by the recipients' cues or communicative signals toward their goals. One possible explanation is that they might lack some cognitive skills necessary to infer what others need or desire in the absence of such communicative signals. This hypothesis finds further support in the results of comparable studies with children.

Specifically, when Brownell and colleagues (Brownell et al. 2009) adapted the apparatus designed by Silk et al. (2005) for children, they found that 18-month-old children (like chimpanzees) chose randomly between a purely selfish and a mutualistic option. Interestingly, 25-month-old

children chose the mutualistic option that rewarded both themselves and the recipient, but only in a condition in which the recipient had verbalized her desire for the food. This suggests that in certain situations explicit communication from the recipient is critical to elicit sharing behaviors, and that a child's failure might not be necessarily due to a lack of motivation, but due to the lack of social-cognitive skills.

Further evidence for the role of social-cognitive skills in helping others comes from three other studies. Although 14-month-old children already show spontaneous, unrewarded helping behavior in simple situations such as handing over out-of-reach objects, they do not help in other type of tasks which might be more complex in terms of the goal-structure and type of intervention necessary to help fulfill the other person's goals and needs. However, throughout their second year of life and after their second birthday, children become increasingly skilled at inferring what others want or need and intervene in a wider range of situations (Warneken and Tomasello 2006, 2007; Svetlova et al. 2010). Therefore, chimpanzees, similar to human children younger than two, might be constrained in helping contexts not due to a lack of motivation to act on the others' behalf but due to an inability to infer the others' needs and desires in the absence of very salient cues.

Collaborative Interactions

In this entry, we review cooperative behavior in which two or more individuals coordinate their behavior to produce outcomes from which all individuals can benefit. Chimpanzees coalitionary support in inter- and intragroup aggressive encounters or cooperative hunts are only some of the examples in which individuals work together to achieve something that is mutually beneficial (Muller and Mitani 2005; Boesch and Boesch 1989). Thus, the motivational basis of collaboration can be totally selfish: agents should be willing to collaborate if the only possibility to achieve an otherwise unobtainable goal is to work together. However, from a cognitive perspective, the question arises to what extent individuals are able to identify the opportunity to combine efforts with a

partner, using different behavioral and communicative means to guarantee successful coordinated actions. Furthermore, in the case of group-level collaboration, temptations for defection arise, and thus cognitive capacities to select trustworthy partners and avoid cheaters are key to maintain collaboration. Thus, differences in the cognitive skills across species might in part explain the differences observed in the flexibility with which species engage in mutualistic collaboration.

Pioneering experiments on chimpanzees found only very limited collaboration skills. Chimpanzees mostly failed to retrieve food rewards when collaboration was required (Crawford 1937; Chalmeau 1994; Povinelli and O'Neill 2000; see Melis et al. 2010 for more details on these initial studies). One interpretation of these results was that cognitive constraints prevented individuals from coordinating actions with the partner (e.g., Povinelli and O'Neill 2000). However, research conducted with other primate species suggested that successful cooperation might not only require a certain level of social cognition, but also tolerance between potential cooperative partners (e.g., Tonkean macaques: Petit et al. 1992; capuchin monkeys: de Waal and Davis 2003). Furthermore, a study by Chalmeau and colleagues showed that the cooperative behavior of their chimpanzees was limited by social constraints on the subordinates (Chalmeau 1994). Specifically, the most dominant individual monopolized the apparatus, thereby preventing others from potentially cooperating. This suggested that in cooperative problem-solving experiments, chimpanzees treated the situation as a competitive one, and that low levels of social tolerance could be affecting chimpanzees' ability to cooperate with others – especially in food retrieval contexts.

Building upon these findings, Melis and colleagues (Melis et al. 2006a) systematically varied tolerance levels by pairing individuals either with a low-tolerance or a high-tolerance partner. Pairs of chimpanzees were presented with an out-of-reach baited tray, which required that they both pull simultaneously (see Fig. 2a). Strikingly, when subjects were paired with partners they could not share food with; they never succeeded in pulling the tray. This was even the case when the food

rewards on the tray were in two separated dishes and thus each individual had a fair chance to obtain food. However, all subjects immediately succeeded when they were paired with a tolerant partner they could share food and co-feed with. However, when food items were clumped in one position and could thus be easily monopolized, chimpanzee cooperation started falling apart. Interestingly, this does not appear to be the case with bonobos, who succeed in the same pulling task equally often whether the rewards are clumped in one location or dispersed (Melis et al. 2006a; Hare et al. 2007). When the same study was conducted with 3-year-old human peers, results showed that peers collaborate and share at very high levels even when rewards are clumped, suggesting that tolerance constraints in children are not as severe as among chimpanzees (Warneken et al. 2011). The results of these studies suggest that we differ from chimpanzees but share with bonobos a more social tolerant nature over food (see also Hare and Kwetuenda 2010).

Taken together, these studies show that under the right circumstances, chimpanzees are able to work together toward mutualistic outcomes. But what level of understanding do chimpanzees bring to the situation? In other words, do individuals intentionally coordinate their actions with those of their partner or is success the by-product of uncoordinated individual efforts? In Melis et al. (2006b) most individuals learned within a few trials to wait for each other in the plank-pull task, delaying their own pulling of the rope until the partner was in position. The task required true synchronization, because otherwise the rope slipped out of the apparatus. In addition, in a more difficult version of the test, individuals could choose to recruit a partner by opening a door for the other to enter the testing area. Subjects recruited the partner significantly more often when the task required cooperation than when the task could be solved individually, showing an understanding of the role of their partner to succeed. Furthermore, when given the choice between two different collaborative partners, they preferentially recruited the more skillful one (See Fig. 2). Taken together, these results

demonstrate that chimpanzee cooperation is not just the by-product of independent individual actions that happen to converge, but that individuals do intentionally coordinate their behavior with that of a partner and choose collaboration as a means to reach goals they cannot achieve individually.

Tomasello et al. (2005) proposed that human collaboration differs fundamentally from chimpanzee collaboration because the former is based upon shared intentions. Shared intentionality is characterized not only by cognitive skills that allow individuals to coordinate actions in pursuit of the shared goal, but by a unique motivation and commitment to collaborate with each other in pursuit of that goal. Studies with children have operationalized this motivation and commitment to collaborate in different ways. For example, if among two collaborating partners one individual stops performing her role, individuals will try to communicatively reengage the partner (Ross and

Lollis 1987; Warneken et al. 2006). Furthermore, children are more likely to reengage the partner if she has previously expressed the commitment to collaborate (“Let’s play together”), which suggests that they treat the other person as an agent with intentions to collaborate or not, and not just as a social tool (Gräfenhain et al. 2009). Second, Hamann et al. (2012) have found that children are not only committed to engage in a collaborative task until one individual is successful, but that there is actually a mutual commitment to ensure that the partner also reaches her goal. In this study pairs of children worked jointly lifting a bar so that each kid could access her own reward. When one of the kids was able to access her reward before the second one could access hers, 3-year-olds (but not 2-year-olds) were more likely to provide support so that the partner could also access hers, and they did this more than in a control condition without prior collaboration. This indicates that 3-year-olds appreciate the commitment for mutual support

Primate Prosocial Behaviors,

Fig. 2 Experimental setup and results of Experiment 2 of Melis et al. (2006b): (a) subjects were given the choice between recruiting a skillful and an unskillful collaborative partner. Subjects needed a partner to pull within reach the baited tray. (b) Subjects preferentially recruited the skillful partner

that characterizes collaboration. Last but not least, children seem to enjoy the collaborative activity in and of itself since they insist on the social nature of the game, reengaging a social partner even when the other person's involvement is not necessary for the child to succeed with the game (Warneken et al. 2012).

Recent studies with chimpanzees do not seem to suggest that chimpanzees' collaborative interactions are based upon joint intentions. Rather, the data so far is rather consistent with the hypothesis that chimpanzees view their partner as a social tool to reach their own individual goals. Specifically, one study by Warneken et al. (2006) used an "interruption method" with human children and chimpanzees: a human experimenter who had previously worked successfully on a mutualistic task stopped playing her role during certain predetermined interruption periods. Chimpanzees consistently attempted to solve the task by their own means or disengaged completely from the task, and never produced any communicative signals to influence their partner's behavior. However, in the same study children regularly employed different communicative means to reengage the partner. An experiment with conspecific dyads provided similar results, as subjects did not communicate with a recalcitrant conspecific partner (Hirata and Fuwa 2007).

Second, Greenberg and colleagues, using a method similar to Hamann et al. (2012), investigated whether chimpanzees appreciate the commitment for mutual support that characterizes collaboration (Greenberg et al. 2010). This study investigated whether partners in a collaborative activity are mutually committed to ensure that both partners succeed in obtaining their goal. Specifically, in a variation of the plank-pull task, two chimpanzees had to pull together to access food rewards. In a collaborative condition, both chimpanzees pulled a board with two rewards, but one "lucky" individual was able to access the reward before the partner could access his. In a non-collaboration condition, one individual could retrieve the reward without prior collaboration ("lucky"), whereas the "unlucky" chimpanzee needed the other's help to pull the board to the

end. Interestingly, results showed that the "lucky" individual helped the "unlucky" individual in approximately a third of trials by jointly pulling the board with her toward the end, even though she had already accessed hers and she would not receive any further reward for pulling to the end. However, this help was provided equally often in both the collaborative and the non-collaborative condition. Thus, chimpanzees were willing to help the other chimpanzee, but in contrast to human children, collaboration did not seem to enhance helping.

Last but not least, even if chimpanzees are willing and able to join efforts when the situation requires it, they do not seem particularly motivated to act together with a partner unless this is the only way to access their goal. In another study which also used the plank-pull task chimpanzees were given the choice between working either individually or collaboratively with a tolerant partner (with both options resulting in equal payoffs for the subjects). Chimpanzees preferably chose the nonsocial option and only shifted their preference to the social-collaborative option when the payoffs of this latter option were higher. This shows that chimpanzees are strategic and cognizant of their collaborative options, but do not seem to be particularly inclined to collaborate with others (Bullinger et al. 2011).

Taken together, the results from these different studies suggest that chimpanzees are able to engage in quite sophisticated mutualistic collaborative activities, including an understanding of when a partner is needed and which partner might best be suited to solve a mutualistic task. However, the current evidence supports the hypothesis that they view their partner as a social tool rather than forming "joint" goals with him and developing joint intentions and a commitment to pursue that goal.

Future Directions

- What enforcing mechanisms sustain altruistic and collaborative behaviors in nonhuman apes?

- To what extent do empathy and sympathy play a role in the observed altruistic behaviors of chimpanzees?
- What are the similarities and differences in the cooperative behaviors of chimpanzees and bonobos as our two closest living primate relatives?

³Department of Psychiatry, University of Groningen, University Medical Center Groningen, Groningen, The Netherlands

Synonyms

Innate reflexes

Definition

Primitive reflexes are patterns of movement that are evoked by specific sensory input. They are complex, automatic movements controlled by the brainstem that can be seen as early as the 25th week of gestation. The primitive reflexes are considered a normal part of infant movement (Zafeiriou 2004). The primitive reflexes include the Moro (a distinctive startle response), the walking/stepping, the rooting, the sucking, the tonic neck (arm straightening in response to turning of the head), the palmar grasp, the plantar or Babinski (toe curling when the sole of the foot is stimulated), the Galant (sideward flexing of the back toward stimulation), the swimming, and the Babkin (head and facial responses to pressure to both palms) reflexes. During the first year of life, the reflexes typically disappear or are more difficult to elicit and their persistence or appearance after infancy is thought to be due to reduced inhibition of brainstem reflexes by the cortex and subcortical regions. Primitive reflexes in older children and adults have been associated with severe neurological problems including

cerebral palsy, acquired brain damage, and stroke (Go and Konishi 2008).

Primitive reflexes, including the snout, sucking, grasp, and rooting reflexes, have been studied in children and young adults with autism (Minderaa et al. 1985; De Bildt et al. 2012). Two thirds of the individuals with autism and none of the control subjects displayed the visual rooting reflex (VRR) to a waving reflex hammer. Neurologists and developmentalists have thoroughly studied the rooting reflexes (Ingram 1962), and they are defined as an orientation toward touch in the area around the mouth region or toward visual stimulation near the face (Schott and Rossor 2003). Although termed a primitive reflex, the VRR has not been described in infants. Rather, most prior reports of the VRR have to do with assessing its presence in adults with various types of neurological dysfunction (Turner and Schon 2006). Further research is needed to characterize more completely the presence and persistence of primitive reflexes in autism and related disorders.

Princeton Child Development Institute (PCDI)

Susan Hepburn

Department of Psychiatry and Pediatrics, JFK Partners, University of Colorado at Denver, Aurora, CO, USA

Colorado State University, Department of Human Development and Family Services, Fort Collins, CO, USA

Definition

The Princeton Child Development Institute (PCDI) is a research-based intervention program for persons with autism of all ages. Located in Princeton, New Jersey, the PCDI is a private, nonprofit organization which collaborates with the New Jersey Department of Education and the Division of Developmental Disabilities to provide a variety of programs, including early intervention, accredited preschool- and school-aged programs, residential services, and adult skill-building programs. Training, dissemination, outreach, and intervention science are integrated within the professional activities of PCDI. Faculty of the institute maintain academic affiliations with Queens College of the City University of New York, the University of Kansas, and the University of North Texas, enabling PCDI to serve as a training site for professionals in the field of developmental disabilities and intervention science.

Historical Background

The PCDI was founded in 1970 by Peggy W. Pulleyn and Pamela Machold. Both women were family members of a young boy with autism and were frustrated by the lack of evidence-based intervention available in their community. Committed to providing educational programs that were based in applied behavior analysis, the institute established the first community-based program

to serve children with autism in the state of New Jersey. In 1975, two leaders in the field of applied behavior analysis – Patricia J. Krantz, Ph.D. and Lynn E. McClannahan, Ph.D. – became codirectors of the Institute and worked to expand its mission to include parent support and education, home-based intervention, and unique residential programs with a “family-like” atmosphere for young people with autism. Under the current leadership of Edward C. Fenske, Ed.S. and Gregory MacDuff, Ph.D., programs based on the PCDI model are growing both nationally and internationally.

Rationale or Underlying Theory

The PCDI provides interventions that are based on the principles of applied behavior analysis (ABA). Data-based instruction, systematic teaching approaches, opportunities for frequent practice of new skills, and active engagement of the learner in highly motivating learning opportunities are the cornerstones of this educational approach. Teaching is dynamic, with close monitoring of the learner’s behaviors so that quick adaptation of teaching techniques, settings, prompts, and reinforcement schedules encourages continual educational progress. A family-focused approach to care is foundational to practice and outreach efforts are directed towards community awareness and integration for persons with autism.

Goals and Objectives

The mission statement of the PCDI (as stated in their website at <http://www.pcdi.org/AboutUs/index.asp>, accessed February 21, 2011) is: “The mission of the Princeton Child Development Institute is to provide effective science-based intervention for children and adults with autism and, through research and dissemination, to extend treatment resources to people with autism, both nationally and internationally.”

Treatment Participants

Individuals with autism across the age range (and their family members) participate in services

provided by the PCDI. Toddlers (i.e., children younger than 2 years of age) can access home-based and/or center-based services. Preschool-aged children and those in elementary and secondary schools receive educational programming through a collaboration with the New Jersey Department of Education. Adults can participate in supported employment and life skills educational programs provided by PCDI and funded by the New Jersey Division of Developmental Disabilities. PCDI currently operates the Family Focus Residential Programs, which provide family-style group home supports to persons with autism of all ages. Parent and Sibling Support Programs are also offered to participating families.

Treatment Procedures

Interventions being implemented and studied at the PCDI are based in applied behavior analysis. Publications by the lead faculty are focused upon developing positive behavioral routines, providing visual and physical structure to encourage independence and success, systematically fading supports to promote mastery, and actively planning for generalization of skills across settings, tasks, and people. Positive behavior supports, direct instruction, naturalistic instruction, and data-based decision-making are all practiced. Programming is individualized to fit the needs of a particular student and family.

Efficacy Information

Several interventions practiced at PCDI are listed as meeting the criteria for evidence-based practice by the National Professional Development Center on Autism Spectrum Disorders, which is funded by the Department of Education to investigate and describe evidence-based procedures (see <http://autismpdc.fpg.unc.edu>).

The PCDI has been recognized for significant contributions to the field by the Journal of Applied Behavior Analysis, Senate of the State of New Jersey (1988, for commendable service to persons with autism), National Teaching-Family

Association (1989, Outstanding Contributions in Education), Division 25 of the American Psychological Association (Fred S. Keller Award for Distinguished Contributions to Behavioral Education, 1992), and the Association for Behavior Analysis (1999, Award for Enduring Programmatic Contributions in Behavior Analysis).

Qualifications of Treatment Providers

Treatment providers are well trained in applied behavior analysis and hold degrees in education, speech and communication sciences, and the behavioral sciences. Faculty are affiliated with several universities, and training opportunities are available for qualified professionals.

Private Speech

Brynn Thomas

The Neurodevelopmental Disabilities Laboratory, Laboratory for Understanding Neurodevelopment (FUN Lab), Northwestern, and the University of Notre Dame, Chicago, IL, USA

Synonyms

[Self-talk](#); [Speech-for-the-self](#)

Definition

Private speech refers to a group of vocalized utterances, typically seen in children from 2 to 7 years old, used as a form of self-regulation. Eventually, these utterances, which are intended for oneself and not others, are internalized and become inner speech. Children with autism use private speech as

a tool for behavioral and cognitive self-regulation as well as thinking and self-organization.

Synonyms

[Proactive inhibition](#)

Definition

Proactive Interference is a well-known and classic phenomenon in the study of human memory and learning. The effects of both prior or subsequent learning observed in the retention of new material not only challenged previous theories and explanations of how one forgets (e.g., decay theory) but turned out to be generally accepted as major determinants of forgetting (Baddeley 1990). Proactive interference refers to the fact that learning which occurs prior to a subsequent event affects the ability to recall it, by decreasing the retention rates. Classical experimental demonstrations can be found in the work of Underwood and colleagues (e.g., Keppel and Underwood 1962), both in short- and long-term memory, where the greater the amount of lists of words (or single words) that are previously learnt by the participants, the greater the forgetting. Some variables are known to modulate this effect, that is, variables that have the ability to reduce or boost forgetting. One of these demonstrations comes from Wickens and colleagues' work (e.g., Wickens 1970). In this experimental study, participants were presented with a triad of words of the same category, over several trials. Of interest is the fact that, besides the expected decrease of recall over trials of the same semantic category (e.g., food words) (build up effect), when the category of belonging of the word triads changed (e.g., to house-part words) there was an observable increase in recall reaching the initial levels of retention (release effect).

Drawing an analogy between, on the one hand, the pattern of preserved and intact functions within the domain of memory that is commonly found in amnesic patients and, on the other hand, the characterization of memory functioning in individuals with ASD, Boucher and Warrington (1976) put forward the hypothesis that autism could be described as an amnesic disorder. Since then, a great deal of research has been carried out regarding mnesic processes in ASD, namely, in the evaluation of proactive interference effects. In a set of two experiments, Carmo and colleagues (Carmo et al. 2016) replicated the paradigm used by Wickens (1970) with a group of high-functioning individuals with ASD to directly test

the presence of proactive interference. These authors found a robust and consistent proactive interference build up effect, with a steady decrease in the amount of recall over trials, similar to that of matched control participants. The release effect when shifting between semantic categories was also present, and thus, proactive interference seems intact in this population and cannot account for the overall reduction in recall rates described by some authors.

University of California Center for Special
Education, Disabilities, and Development, Santa
Barbara, CA, USA

Synonyms

[Fidelity of implementation](#); [Independent variable measurement](#); [Procedural adherence](#); [Procedural integrity](#); [Procedural reliability](#)

Definition

Specific term for monitoring, collecting, and documenting data on the independent variable so that it results in a measure of treatment integrity. It provides individuals with information about the conditions that need to be met for the treatment to produce reliable effects. Typically, procedures are provided in written format, such as a manual. It is critical that procedures are assessed for procedural fidelity for consistency and standardization in replication as well as reducing the possibility that a third variable is responsible for the findings. Furthermore, procedural fidelity data can provide practitioners with useful information regarding implementation of research-based interventions.

Procedural Memory

Joshua Ewen and Stewart Mostofsky
Kennedy Krieger Institute, Baltimore, MD, USA

Definition

Procedural learning refers to the process by which skills are acquired implicitly (without conscious recall) through repeated exposure to and practice of a task (Squire 1986).

Historical Background

The discovery of the disassociation between memory that could be expressed verbally and accessed consciously (i.e., declarative memory) and experience-based brain adaptation that occurred implicitly (i.e., procedural memory) developed principally from the study of amnesic patients in the 1970s (Squire 1986). As discussed in Current Knowledge, in the intervening decades, a number of paradigms have been developed to

assess various manifestations of procedural learning. The number of studies explicitly investigating procedural learning in autism has increased over the last few years.

Current Knowledge

Introduction

Procedural learning forms the basis for the development of many cognitive and behavioral skills and is understood to result from plasticity in action-oriented brain systems (Gidley Larson and Mostofsky 2006). Motor/premotor circuits in particular have been shown to play a role in the development of many types of skills via procedural learning. Motor skill development is the focus of much procedural learning research, both because motor learning represents the “classic” understanding of procedural learning and because motor responses can be measured reliably. Nevertheless, there is also strong evidence that demonstrates the role of procedural learning in communicative (Ullman 2004) and social skill development (Lieberman 2000).

Autism is characterized by impairments in a number of skilled behaviors necessary for effective social and communicative functioning. Nearly all individuals with autism show substantial delays in adaptive functioning, even in the face of normal general intelligence. Additionally, clinical experience reveals that many children with autism show relative strength in ability to memorize facts and “scripts” (i.e., through separate, declarative learning systems), yet they have difficulty implementing experience-dependent, contextually based (i.e., procedurally based) strategies to deal with social situations and activities of daily living. One potential source of this functional disassociation is a cognitive disassociation between impaired procedural learning and spared (or even superior) declarative learning in autism. The discrepancy between intelligence and adaptive functioning suggests that autism may be specifically characterized by problems with learning “how to” engage in a wide range of skills necessary for social, communicative, and motor functioning, namely, impairments in procedural learning.

Given known skilled motor deficits in autism as well as the fact that much of motor skill development is associated with procedural learning, the study of motor impairment in autism may be critical to understanding the procedural learning basis of the autistic phenotype. Substantial and accumulating evidence demonstrates that a strong preponderance of children with autism display impairments in motor function, with particular impairments in the performance of *skilled* motor gestures (Dziuk et al. 2007; Mostofsky et al. 2006). As autism is a developmental disability, it follows that the impaired performance of skilled motor gestures results from impairments in the procedural learning of those motor skills (Gidley Larson and Mostofsky 2006).

These alterations in the development of motor, social, and communicative skills make the examination of procedural learning a desirable target of research. Several investigators have begun to examine procedural learning in autism. Although a variety of tasks used for the study of procedural learning have failed to show group differences between individuals with autism and controls, approaches that focus specifically on motor learning have shown robust effects. A picture is emerging that demonstrates the role of altered skill learning in the autism phenotype.

Procedural Learning: Phenomenology

The concept of procedural learning refers to brain adaptation that is responsive to repeated exposure to and practice of a task and occurs without the individual’s awareness (Squire 1986). This is sometimes referred to as “learning how,” whereas declarative learning, which consists of the acquisition of knowledge that occurs with awareness and can often be expressed linguistically, is sometimes referred to as “learning what.” When considering the complex relationship between procedural and declarative learning, it is important to consider that “procedures” that can be expressed by the individual as semantic concepts (i.e., “first do this, then do that”) exist in the brain as products of *declarative* learning rather than procedural learning. This consideration is particularly critical when studying tasks that purport to examine procedural

learning, as reliance on declarative mechanisms may produce a significant confusion.

There is a complex literature on declarative learning in autism, some of which suggests normal or even superior skills. Romero-Munguía has proposed the not-yet-validated “mnestic imbalance” theory of autism, in which it is the discrepancy between procedural learning deficits and spared declarative learning skill that produces the core features of autism (Romero-Munguía 2008). Specifically, the theory suggests that core impairments in behavioral flexibility are caused by deficits in the development of automatic actions and in prototype formation, which subsequently leads to impaired social and communicative skills. A preserved or even superior declarative memory allows for preferred activities, such as memorizing encyclopedias. Although there is not much experimental evidence yet to accept or reject this hypothesis, the underlying rationale suggests ways in which altered procedural learning could result in the core features of autism.

Motor Deficits in Autism: A Key to Recognizing Procedural Learning Impairments

Evidence that impairment in procedural learning may be affected in autism comes from the study of the motor system. Motor deficits have been recognized since Kanner’s initial description of autism (Kanner 1943) and have been the focus of increased investigation over the past few decades. While abnormalities of basic motor control have been reported (Jansiewicz et al. 2006; Rinehart et al. 2006), it is impairment in performance of *learned*, complex motor skills which has been most consistently described (Dowell et al. 2009; Dziuk et al. 2007; MacNeil and Mostofsky 2012; Mostofsky et al. 2006). Parents often report that their children with autism showed normal acquisition of early basic motor milestones such as sitting up and walking, but then showed delays in the acquisition of complex motor skills that rely on intact mechanisms of procedural learning. Impaired performance of complex motor skills appears to be specific to autism, even when compared with conditions such as attention deficit/

hyperactivity disorder (ADHD), in which there is known impairment of basic motor control (MacNeil and Mostofsky 2012; Mostofsky et al. 2010).

It is further possible that impaired procedural learning is directly relevant to impaired development of social and communicative skills in autism. On a theoretical level, but one that is informed by experimental data from healthy subjects and a range of clinical groups, it is thought that procedural learning mechanisms are critical for both language development (Ullman 2004) and development of social competency (Lieberman 2000). In research specific to autism, it has been demonstrated that there is a correlation between degree of impairment in complex motor function and degree of impairment in core social and communicative skills (Dziuk et al. 2007). The acquisition of social and communicative skills by procedural learning mechanisms may be further impaired in autism by deficiencies of the systems which are believed to generate the inputs and feedback for the learning of these skills. Specifically, “embodied cognitive science” suggests that social and communicative skills are acquired at least in part through an individual’s ability to implicitly model another’s actions in order to understand intent and emotional state (Klin et al. 2003); these skills are known as theory of mind, which is impaired in autism (Baron-Cohen et al. 1985; Williams 2008). This intention understanding has been linked to the so-called mirror neuron system (MNS) (Williams 2008).

Neurobiology of Procedural Learning

Procedural learning depends on frontal (motor and premotor)-parietal circuits important to establishing sensory-motor representations, as well as input from the basal ganglia and cerebellum, which provide reward-based and error-based feedback, respectively, both of which are critical to skill-based learning (Keele et al. 2003; Shadmehr and Krakauer 2008). There is considerable evidence that frontal-parietal connectivity (and therefore frontal-parietal network function) is decreased in autism (Just et al. 2007; Mostofsky and Ewen 2011). Connections between premotor and posterior parietal cortex are implicated not

only in procedural learning but also in the subsequent expression of previously learned skilled gestures (i.e., praxis) (Geschwind 1965; Wheaton and Hallett 2007) and in the imitation of both meaningful and novel gestures (described as comprising a “mirror neuron system”) (Iacoboni and Mazziotta 2007). The topographical overlap among circuitry involved in procedural learning, praxis, and motor imitation suggests that examination of procedural learning is key to understanding the developmental basis for well-documented autism-associated impairments in imitation and praxis (Dziuk et al. 2007; Mostofsky et al. 2006; Williams 2008). Socialization and communication are largely dependent on both the execution of these skilled actions as well as the ability to interpret these actions when performed by others. Procedural learning may thereby also be important to understanding the processes by which the core features of the autism phenotype develop.

Direct Examination of Procedural Learning in Autism

There have been direct experimental investigations of procedural learning in autism using a range of approaches. The concept of procedural learning encompasses a number of different capabilities, and the cognitive and neurobiological similarities and differences of these capabilities have not been fully resolved. There are experimental paradigms commonly used to examine many aspects of procedural learning, including motor adaption and sequence learning as well as category learning. The SRTT is perhaps the most commonly used experimental task for assessing implicit sequence learning (Robertson 2007). To perform the SRTT, the participant observes a screen that displays a sequence of stimuli and then presses the corresponding buttons in order. Reaction time and error rates are recorded. The stimuli are presented with a pattern imbedded in the order of presentation, so implicit learning of the pattern results in a progressive decrease in reaction time, as well as error rate. One early study of the SRTT in autism (Mostofsky et al. 2000) showed a typical pattern of progressively decreasing response times in control children but a stable pattern of response times in children with

high-functioning autism, suggesting impaired implicit sequence learning in autism. In several training periods that occurred over a 6-week period, Gordon and Stark (2007) demonstrated a decreased learning effect using the SRTT in children with low-functioning autism. On the other hand, there have been a number of studies which have found no difference between children with autism and controls (Barnes et al. 2008; Brown et al. 2010; Muller et al. 2004; Nemeth et al. 2010; Travers et al. 2010). It is likely that methodological concerns are responsible for the differing conclusions. A criticism of the SRTT approach is that it may measure sequence learning rather than motor learning (Robertson 2007) and therefore may not tax the systems that are altered in autism.

Two examinations of a contextual cueing task also showed no group differences (Barnes et al. 2008; Brown et al. 2010). Contextual cueing is a visual search task, where implicit patterns of distractors give a “hint” as to whether the target is present. An artificial grammar task, in which strings of letters with an implicit “grammatical” pattern are memorized, failed to show group differences (Brown et al. 2010). Similarly, a probabilistic classification learning task, where aspects of the stimuli (in this case, the clothing of a cartoon character) had a probabilistic relationship to the correct classification of the character, showed no differences by diagnosis (Brown et al.).

Approaches to Examining Motor Learning in Autism

Perhaps the greatest insights into the association between procedural learning and the autism phenotype have come from examination of motor learning. Recent theoretical perspectives of motor learning specify “internal models” as motor programs that encode discrete motor actions (Iacoboni and Mazziotta 2007; Mostofsky and Ewen 2011; Shadmehr and Krakauer 2008). As described, the formation of internal models of action is critical to learning skilled movements, as well as to learning to interpret others’ movements. Children with autism display impairments in both these domains, with well-documented difficulty in performing skilled actions (i.e., dyspraxia), as well as with recognizing and correctly identifying

those actions when performed by others (Baron-Cohen et al. 1985; Dowell et al. 2009). This suggests that anomalous formation of internal models of action may be important to understanding the patterns of motor and social deficits associated with autism. Consistent with this, children with autism show a strong association between the severity of dyspraxia and the severity of core impairments in social and communicative behavior (Dziuk et al. 2007).

Investigators have begun to examine patterns of action model formation in autism, initially focusing on tasks that test motor adaptation, or the ability to learn a novel pattern of movement based in response to a discrete sensory perturbation. In a particularly revealing study, Haswell et al. (2009) used a motor adaptation task in which participants used a joy stick to move a cursor on a computer screen situated horizontally in front of them so that it obscured the joy stick from their view. In a series of trials, participants used the joy stick to make a reaching motion, extending their arm toward a target. During most trials, a force perpendicular to the participant-controlled direction of movement was applied to the joy stick so that participants had to learn to adapt their arm motion in order to hit the target. After this learning phase of the task, the screen and controller were moved. The relationship of the controller movement to the cursor movement was changed in one of two ways. In the first, the coordinate system relative to the visual input (Cartesian coordinate) was maintained; in the second, the coordinate system relative to proprioceptive input (joint position) was maintained. The findings revealed that, as compared with control subjects, children with autism spectrum disorders showed markedly increased generalization when the proprioceptive coordinate system was maintained and showed decreased generalization (persistence of motor adaptation) when the visual coordinate system was maintained. Furthermore, the strength of increased reliance on proprioceptive input robustly correlated with impairments in imitation, praxis, and social competence, suggesting that alterations of motor adaptation may share a neurobiological basis with the core symptoms of autism (Haswell et al. 2009). Moreover, these

alterations of patterns of motor adaptation generalization were specific to autism and were not seen in children with ADHD (Izawa et al. 2012).

The findings from these studies of motor adaptation suggest that when learning a novel action, children with autism show a bias toward relying on proprioceptive input from their own “internal” world rather than visual input from the external world around them. Indeed, previous investigators had suggested that children with autism respond more effectively to proprioceptive rather than visual input (Masterton and Biederman 1983). Furthermore, these observations are in keeping with recent influential connectivity theories (Horwitz et al. 1988; Mostofsky and Ewen 2011), in which autism is postulated to be associated with an overgrowth of short-range connections (including those between primary somatosensory and motor cortices that encode proprioceptive feedback) and an undergrowth of longer-range connections (including those between inferior parietal and premotor cortices that encode visual feedback).

The correlation between motor learning ability and social/communicative competence (Dziuk et al. 2007; Dowell et al. 2009; Haswell et al. 2009; Izawa et al. 2012), as well as the fact that similar frontal-parietal networks are understood to underlie both types of skill, suggests that the brain systems necessary to acquiring and maintaining motor skills (praxis) may parallel (and perhaps overlap) those systems necessary to acquiring and maintaining social/communicative skills. In this light, autism could be viewed as a “developmental dyspraxia” of social and communicative function (Mostofsky and Ewen 2011), such that anomalous patterns of internal action model formation contribute to both impaired development of motor/social/communicative skills, as well as impaired ability to understand these actions when performed by others.

Summary

In summary, there is a compelling theoretical basis, both neurobiological and cognitive/behavioral, to suggest that impairments of procedural

learning are both present in autism and causally related to the core symptoms. Evidence to date using standard paradigms has, to a large degree, failed to demonstrate these impairments. Novel approaches that target specific known deficits in autism, however, may hold the key to relating alterations of procedural learning to the autism phenotype. This course of investigation could lead to crucial insights into the brain basis of autism and provide a foundation for advancing therapeutic strategies targeting autism-associated difficulties with social, communicative, and motor skills.

Future Directions

Findings generated from studies of procedural learning could lay the foundation for novel approaches for therapeutic interventions targeting improvements in motor, social, and communicative skills. This approach has the potential to provide crucial advances, as current therapeutic techniques (e.g., speech-language therapy, behavioral therapy, educational interventions) often depend on procedural skill learning. One approach under investigation involves “playing to the strength” of children with autism by teaching skills such as handwriting or sign language to children with autism using increased haptic (proprioceptive) input rather than the typical approach that relies on imitating others’ actions (Feder and Majnemer 2007). This approach of increasing proprioceptive input may help children with autism improve specific motor skills; however, it is unlikely to help these children learn social skills given that social interaction involves modeling others’ visually observed behavior. It will therefore be crucial to also explore both behavioral and electrophysiologic methods for enhancing visual-motor connectivity in children with autism.

Procedural Safeguards

Debra Dunn

The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

Parent protections

Definition

Procedural Safeguards are protections afforded by the Individuals with Disabilities Education Improvement Act of 2004 (IDEIA) to each student with a disability and to his or her parents to

ensure that the student receives a free and appropriate public education. The Procedural Safeguards ensure that parents (or the student if the student has reached the age of majority within the state) are notified of their rights to and the procedures for disagreeing with the special education process.

The safeguards afforded parents: the rights to examine all of the student's records, to participate in meetings regarding the identification, evaluation, and placement of the student, to consent to evaluations and the provision of special education services, to obtain an independent educational evaluation when needed, and to present and resolve a complaint. The Procedural Safeguards also grant parents the right to written notice within a reasonable time frame when the local education agency (typically the school) wants to evaluate a student, determine whether a student is eligible for special education services, change a student's evaluation, educational placement, or individualized education program (IEP), or refuse a parent's request to evaluate a student or change a student's IEP or placement. While some changes in placement are obvious (for example, a change from a regular education classroom placement to an autism support classroom), the IDEIA specifies certain less common situations that may constitute a change of placement, including removal to an alternate educational setting due to violations of a code of student conduct.

To help educate parents about their rights, schools must provide parents with a procedural safeguards notice at least once a year. Additional notices must be provided whenever a student is referred for an initial evaluation, when a parent requests a new evaluation, at the time a due process complaint is filed, or whenever a parent requests a copy. The notice must detail the process by which a parent may present and resolve complaints related to the special education process, including the option of voluntary mediation. Because states are at liberty to develop ways to implement the IDEIA, the procedural safeguards notices vary from state to state. The actual protections contained within the notice, however, may not confer fewer rights to parents and students than what is provided for by the IDEIA.

Processing Speed Index

Timothy Soto
Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Synonyms

Processing speed quotient

Definition

Processing speed refers to the speed of cognitive processes and response output. The Processing Speed Index (PSI) is one of four indices that make up the full scale intelligence quotient (FSIQ) derived from The Wechsler Adult Intelligence Scale-4th edition (WAIS-IV) and The Wechsler Intelligence Scale for Children-4th

edition (WISC-IV), primary standardized clinical instruments used to measure intelligence. The tasks included in the scales that comprise the PSI, (Coding, Symbol Search), are timed and require attending to visual material, visual perception and organization, visual scanning, and hand-eye coordination. Performance on the Coding subtest also requires paired associative learning. Anxiety and fine motor problems may interfere with performance on the PSI. Coding, in particular, which requires copying simple shapes, may be affected by motor output problems. This tends to be an area of relative weakness for children with ASD (Calhoun and Mayes 2005).

Processing Speed Quotient

Timothy Soto

Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Synonyms

[Processing speed index](#)

Definition

The Processing Speed Quotient is one of the four indices of the Wechsler Preschool and Primary Scale of Intelligence-Third Edition (WPPSI-III). The other three are Verbal, Performance, and Full Scale Intelligence Quotients. The Processing Speed Quotient measures mental and visual-motor processing speed and accuracy for individuals aged 4 through 7 years. The Processing Speed Quotient is made of two subtests: Symbol Search and Coding and provides an estimate of a child’s ability to quickly and correctly scan, sequence, and discriminate simple visual information. This tends to be an area of relative weakness for children with ASD (Calhoun and Mayes 2005).

Profile of Intelligences

Sara Kaplan-Levy and Shirley Poyau
Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

A profile of intelligence is a way of presenting multiple scores earned on a cognitive assessment in relation to one another. The scores may include specific subtests, composite indices, and a full-scale intelligence quotient score (FSIQ). The profile of intelligence also depicts the scatter, or the pattern, of scores on a cognitive assessment.

Historical Background

In the past, psychologists analyzed profiles of intelligence to diagnose individuals with particular learning styles or disabilities. However, these diagnoses were not always clinically or psychometrically sound, as subtest scores are not as reliable as index scores, and the subscales of cognitive assessments often assess intersecting cognitive abilities (Sattler and Ryan 2009). Due in part to concerns about relying on limited data, the American Psychological Association [APA] (2002) stated that psychologists should not make diagnoses based on data from a single test, though they recognize that a profile of intelligence scores can provide practitioners with a great deal of information about an individual’s distribution of cognitive abilities, or relative strengths and weaknesses.

Current Knowledge

Today, psychologists use profiles of intelligence to create hypotheses about an individual’s cognitive strengths and weaknesses, which they can examine further with additional cognitive evaluations and qualitative interviews. Specific assessments often used with individuals with Autism Spectrum Disorders (ASD) include the Wechsler Preschool and Primary Scale of Intelligence – Third Edition (WPPSI-III; Wechsler 2002) for children 2 years 6 months to 7 years 3 months old, the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV; Wechsler 2003) for children 6–16 years old, and the Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV; Wechsler 1997) for individuals 16–90 years old. The Mullen Scales of Early Learning (Mullen 1995) are also used with very young children.

The WPPSI-III consists of seven core subtests, a composite of which creates the FSIQ. The seven core subtests are Information (test of ability to retain and retrieve knowledge), Vocabulary (test of verbal knowledge), Word Reasoning (test of verbal comprehension and reasoning ability), Block Design (test of visual perception and organization), Matrix Reasoning (test of visual information processing), Picture Concepts (test of abstract reasoning ability), and Coding (test of visual perception and short-term memory). The Verbal IQ score (VIQ) is the composite of Information, Vocabulary, and Word Reasoning scores. The Performance IQ score (PIQ) is the composite of Block Design, Matrix Reasoning, and Picture Concepts. The Processing Speed Quotient (PSQ) is based solely on the Coding score.

The WISC-IV consists of ten core subtests that are used to calculate the VIQ, PIQ, and FSIQ. The ten core subtests are Similarities (test of abstract reasoning), Vocabulary (test of verbal knowledge), Comprehension (test of general principles and social situations), Block Design (test of visual perception and organization), Picture Concepts (test of abstract reasoning ability), Matrix Reasoning (test of visual information processing), Digit Span (test of working memory), Letter-Number Sequencing (test of mental manipulation and short-term memory), Coding (test of visual perception and short-

term memory), and Symbol Search (test of processing and psychomotor speeds and visual short-term memory). Scores on the WISC-IV subtests create four composite index scores: Verbal Comprehension Index (VCI), Perceptual Reasoning Index (PRI), Working Memory Index (WMI), and Processing Speed Index (PSI). VCI is a composite score of Similarities, Vocabulary, and Comprehension; PRI is a composite score of Block Design, Picture Concepts, and Matrix Reasoning; WMI is a composite score of Digit Span and Letter-Number Sequencing; and PSI is a composite score of Symbol Search and Coding.

The WAIS-IV consists of ten core subtests that are used to calculate the VIQ, PIQ, and FSIQ. Nine of the subtests are similar to those previously described in the WISC-IV, but the WAIS-IV also includes Arithmetic (test of working memory and numeric reasoning). Similar to the WISC-IV, scores on the WAIS-IV create four composite index scores: Verbal Comprehension Index (VCI), Perceptual Reasoning Index (PRI), Working Memory Index (WMI), and Processing Speed Index (PSI). VCI is a composite score of Similarities, Vocabulary, Information, and Comprehension; PRI is a composite score of Block Design and Matrix Reasoning; WMI is a composite score of Digit Span and Arithmetic; and PSI is a composite score of Symbol Search and Coding.

Clinical Uses: Practitioners can assess an individual's cognitive strengths and weaknesses by conducting ipsative (i.e., intra-individual) comparisons of an individual's scores or by conducting comparisons to standardized scores (i.e., inter-individual). By taking the difference between index scores, scaled subtest scores, subtests of scaled subtest scores within a broader composite score, and the individual's respective average scores (i.e., ipsative comparisons), practitioners can learn which cognitive skills pose relative difficulty or relative areas of strength for the individual. Considering an individual's scores among those of a standardized group, practitioners can decipher which cognitive skills pose difficulty or areas of strength for this particular individual with respect to the norm group.

By doing thorough profile analyses, and comparing the spread of a person's profile of

intelligence to that of a standardized group, practitioners determine the frequency with which such variability of scores occurs. Knowing how often certain significant differences in index or scaled subtest scores occur in a standardized population, practitioners can begin to create hypotheses about an individual's specific abilities and areas of struggle. For example, if a person earned a PRI score significantly greater than his/her VCI score, practitioners might wonder if the individual's visual-spatial processing and visual-discrimination processing are more developed than his/her verbal processing or auditory-vocal processing. A significant difference between these two index scores could also be a sign of more developed nonverbal problem-solving skills than verbal retrieval of information skills. Although these discrepancies do not establish the presence of a cognitive disability, they do indicate a possible disparity in a person's cognitive abilities and identify cognitive skills that should be further evaluated.

Similarly, significant differences between an individual's scaled subtest scores, especially if they are uncommon in the standardized group, could signify particular cognitive abilities or difficulties. Moreover, comparing scaled scores of two subtests within the same index could reveal important information about the way in which an individual processes information or completes tasks. For example, Vocabulary and Similarities are both subtests of the VCI that measure abstract thinking ability. A significantly greater Vocabulary score than Similarities score might reveal that the individual's knowledge of words is greater than his/her ability to categorize and vice versa if the Similarities score were significantly greater than the Vocabulary score. Again, finding significant differences in scaled subtest scores that are rarely seen within the standardized group is not enough evidence to make declarative statements about a person's cognitive limitations. However, such discrepancies encourage a practitioner to direct attention to these particular cognitive skills, to assess further to determine if a problem exists.

Although it provides little information about variability across subtests, practitioners might

also find it helpful to examine the difference between an individual's highest and lowest scaled subtest scores. A significant range that is rarely found within the standardized group might be an indication of a specific cognitive aptitude or a particular cognitive deficit.

Lastly, analyzing profiles of intelligence in this in-depth manner is essential for determining if the FSIQ is an accurate depiction of a person's overall intelligence. If, in fact, there is a great deal of scatter between scaled subtest scores, then the FSIQ is not interpretable. When examining a profile of intelligence with significant variability, practitioners should administer further cognitive assessments to determine whether the assessment revealed a genuine portrayal of a person's cognitive abilities and to gather information about those cognitive tasks that caused the examinee particular difficulty.

It is critical that practitioners analyze profiles of intelligence after performing cognitive assessments because the pattern of scores provides substantial information about an individual's specific cognitive abilities (e.g., indices, subtests) and areas of struggle; this knowledge allows practitioners to assess more deeply a person's particular areas of, and possible reasons for, difficulty. Practitioners can then synthesize all of the information they have gathered through cognitive assessments with knowledge about the individual that has been collected via medical history and in-person interviews to create personalized suggestions for ways to improve or manage certain cognitive weaknesses. This thorough examination and comprehension of a person's cognitive abilities is essential because, if aid is needed, it allows for the development of individualized plans for support.

Clinical Uses for Individuals with Autism Spectrum Disorders

Practitioners have used profile analysis to determine profiles of intelligence that can be observed among groups of individuals with ASD; researchers have claimed that across the life span, individuals with ASD diagnoses had similar Wechsler Intelligence Scale profiles that were characterized by a lower VIQ than PIQ.

Comprehension was often the lowest subtest score and Digit Span was the highest subtest score on the VIQ composite, while Coding/Digit Symbol was the lowest subtest score and Block Design was the highest subtest score on the PIQ composite (Yirmiya and Sigman 1991). Furthermore, researchers distinguished between individuals with high functioning autism (HFA) and Asperger's Syndrome (AS) using profiles of intelligence: researchers found that individuals with AS had higher VIQ than PIQ, whereas those with HFA were more likely to have a profile similar to those with ASD, with a VIQ lower than their PIQ. Siegel et al. (1996), however, reported on findings from 16 studies of people with ASD and found that while this profile was common among people with ASD, many participants across studies had intelligence profiles that revealed higher VIQ than PIQ. Moreover, the profile of intelligence suggested to be associated with ASD has also been observed among individuals without ASD as well as individuals with language disorders. Siegel et al. continued to suggest that although certain aspects of a profile of intelligence might be common among individuals with ASD, profiles of intelligence are dependent upon an individual's particular abilities, not his/her ASD diagnosis.

Future Directions

As tests are increasingly co-normed, it will be easier to compare scores not only within a single cognitive tool, but across instruments and domains (e.g., intellectual functioning and memory capacities).

Profiling Elements of Prosody in Speech-Communication (PEPS-C)

Sue Peppé
High Appin, Tynron, Thornhill, UK

Synonyms

[PEPS-C](#)

Definition

Profiling Elements of Prosody in Speech-Communication (PEPS-C) is a semiautomated test battery for assessing receptive and expressive prosody skills. It has been used in several studies

of the speech and understanding of children with high-functioning autism/Asperger's syndrome (see section "References and Readings"). It is intended for use by clinicians and researchers in assessing prosody in any conditions in both children and adults. A demonstration of the test can be found on www.peps-c.com.

PEPS-C comprises 12 tasks, addressing receptive and expressive skills in parallel. The tasks are at two levels, examining prosodic function and prosodic form, respectively. PEPS-C defines four main linguistic functions conveyed by prosody, with a receptive and an expressive task for each:

1. Turn end: indicating whether an utterance requires an answer or not (question/statement)
2. Affect: indicating mood/emotions/opinions – in this test, signaling liking or reservation with respect to food items
3. Chunking: prosodic phrase boundaries indicating how speech can be verbally "chunked," as in the difference between "fruit, salad, and milk" and "fruit salad and milk"
4. Contrastive stress or focus: emphasizing one word in an utterance to focus attention on it, e.g., "white COW" as opposed to "WHITE cow"

Prosodic form processing requires non-cognitive skills. The tasks are:

- Two auditory discrimination tasks, essentially same/different tasks. Stimuli exemplify the prosodic variations that convey the different meanings used in the receptive prosodic function tasks.
- Two imitation tasks requiring the production of the types of prosodic variation needed for completing the expressive function tasks.

The assessment of skills at two levels helps to determine the level at which a client has a problem with prosody, thus enabling better targeting of intervention. The test is not standardized, but a limited amount of normative data is available.

Progressive Applied Behavior Analysis

Justin B. Leaf, Ronald Leaf, John McEachin and Joseph H. Cihon

Autism Partnership Foundation, Seal Beach, CA, USA

Definition

Leaf et al. (2016a, d) described the scientific nature of applied behavior analysis (ABA) and that ABA, as a science, and interventions based upon the principles of this science should be *progressive*. A progressive approach to ABA-based interventions contrasts with *conventional* approaches in several ways. Some hallmarks of a conventional approach to ABA are (1) the implementation of interventions by adhering to protocols with little to no variation, (2) routinely conducting a formal functional analysis prior to intervention, (3) routinely using continuous data to measure behavior, (4) having a limited curricular scope (e.g., only focusing on either reduction of aberrant behavior, language development, or academics), (5) and heavy reliance on formal assessments to determine potential reinforcing events. In essence, a conventional approach to ABA-based intervention can be described as protocol driven in that technicians are governed by rules as opposed to being responsive to the individuals with whom they work with.

Contrasting with a conventional approach, the goal of a progressive approach is to utilize a systematic plan during each session but, also, having the freedom to deviate from that plan at any given moment based upon the needs of the client. To do this, the behavior analyst is constantly making in-the-moment assessments to inform changes to the predetermined systematic plan. There are many variables that contribute to what has been described as clinical judgment which include, but are not limited to, (a) moment-to-moment changes in the function of the client's behavior, (b) interfering or aberrant

behaviors, (c) determination of whether behavior is primarily operant or respondent, (d) current levels of engagement, (e) the client's receptivity to learning, (f) the emotional state of the client, (g) current and past performance, (h) ongoing evaluation of reinforcer effectiveness, and (i) the physical health of the client. Furthermore, a progressive approach includes a formal, analogue functional analysis sparingly, if ever (i.e., the behavior analyst is constantly assessing function throughout the session making this type of functional analysis unnecessary) data collection systems are streamlined, curricular targets are comprehensive, and formal preference assessments are rendered unnecessary through in-the-moment reinforcer analysis (IMRA; Leaf et al. 2015, 2016c). In essence, a progressive approach to ABA is one that is characterized by structured flexibility in that the behavior analyst has a systematic plan but has the flexibility to alter this plan through responsiveness to the client (i.e., the behavior analyst is governed by the client's behavior instead of solely by a protocol).

Historical Background

ABA, as a practice, is rooted in the science of behavior analysis which is interested in the effect of environmental variables on behavior. Specifically, ABA, as a science and practice, is interested in the manipulations of these variables to improve socially significant behavior. The history of the science of behavior analysis has been marked by many important contributions that led to the development of the field of ABA. These events have included, but are not limited to, Edward Thorndike's contribution of the law of effect, Ivan Pavlov's contribution of respondent conditioning, John B. Watson's identification of behaviorism as a methodology, and B. F. Skinner's formulation of operant conditioning (see Moore 2008 for a detailed history of behavior analysis). These and many more contributions resulted in Baer et al. (1968) writing a seminal article which defined some important dimensions of ABA. Within their seminal article, Baer and colleagues described ABA as involving at least seven

dimensions which included applied, behavioral, analytic, technological, conceptually systematic (referred to as a conceptual system), effective, and generalizable (referred to as generality). Since 1968, there have been thousands of studies embodying the dimensions Baer et al. put forth to improve socially significant behavior. Today, interventions based upon the principles of ABA are in widespread use for treatment of individuals diagnosed with autism spectrum disorder (ASD) and have the strongest body of empirical evidence demonstrating its effectiveness (Smith and Iadarola 2015).

In the pioneering days of behavior analytic intervention, it was common for behavior analysts to utilize a structured yet flexible approach to intervention. This may have been a result of the dearth of established protocols during these initial years, which required interventionists to be innovative and pay close attention to what is happening in front of them. This flexible approach to intervention is exemplified by many of the early behavior analytic studies such as Wolf et al. (1963) who explored the use of a shaping procedure with a young boy with autism. The shaping procedure was used to successfully decrease tantrums, help with bedtime problems, and increase eyeglass wearing for the participant (Dickey). In another seminal study, Ayllon and Azrin (1965) evaluated the use of a token economy to improve the behavior of patients at a mental hospital ward. Targeted skills included serving meals, filling water bottles, and answering the telephone. Tokens were delivered contingent upon completion of the tasks, and these tokens were exchanged for a presumed reinforcing item. To identify these potential reinforcers, "No a priori decisions were made about what should be an effective reinforcer. Instead, patients' behavior was used to discover reinforcers" (Ayllon and Azrin 1965, p. 358). Thus, the researchers used in-the-moment assessment to determine what may or may not function as a reinforcer as opposed to conducting a formal preference assessment.

A progressive approach to ABA was also demonstrated by researchers evaluating comprehensive behavioral intervention for individuals diagnosed with ASD. For instance, Lovaas et al. (1973)

and Lovaas (1987) provided comprehensive intervention using a variety of behavioral techniques (e.g., discrete trial teaching, incidental teaching, and shaping) to improve the participants' cognitive skills, language skills, play skills, and reduction of aberrant behavior. The intervention in both studies was comprehensive in scope and intensive (e.g., providing an average of 40 h of intervention per week). The results of these studies demonstrated that comprehensive and intensive behavioral intervention resulted in children making significant gains on standardized assessments (e.g., IQ scores) and improvements on global behaviors (e.g., educational progress). While professionals may suggest that the approach was conducted in a rigid/conventional manner, those involved in the project described what aligns closer to a progressive approach (Leaf and McEachin 2016). This is illustrated by the lack of set protocols on what to teach, how to teach, the prompting systems used within teaching, or the way data was taken. Thus, two seminal and commonly cited studies in the behavioral treatment of ASD were done using a progressive approach.

Since the Lovaas (1987) report, the number of studies evaluating behavioral interventions for individuals diagnosed with ASD and the number of individuals receiving behavioral services have increased (Dorsey et al. 2009). Unfortunately, this increase has resulted in the manualization of ABA and a de-emphasis on the need for intensive and quality training. As such, many behavior analysts adhere to the latter rather than the intent of manuals and protocols (Leaf et al. 2016d). Today, it is more common to observe a conventional approach to ABA, which contrasts with the early years of ABA during which remarkable outcomes were achieved. In the last 10 years, however, researchers and clinicians have started to evaluate and describe how the progressive approach can successfully be implemented for individuals diagnosed with ASD.

Current Knowledge

There are many examples in the research of evaluations and descriptions of a progressive

approach to ABA-based interventions. In the text below, we will describe some of the current knowledge of the progressive approach and briefly contrast it to a more conventional model.

Reinforcement identification. In a conventional approach, behavior analysts typically conduct formal preference assessments (e.g., multiple stimulus without replacement, paired stimulus, single stimulus) in which one potentially reinforcing item is compared to another or to an array of stimuli. As previously stated, in a progressive approach, the necessity for formal and a priori preference assessment is eliminated. This is done by the frequent use of in-the-moment assessments to determine what stimuli to use as potential reinforcers. Within these in-the-moment assessments, the behavior analyst evaluates multiple variables including affect, verbal and nonverbal behavior, and engagement.

Leaf and colleagues (2015) compared a paired stimulus preference assessment to IMRA on the rate of responding with several children diagnosed with ASD during a simple sorting task. A paired stimulus preference assessment was conducted during which the participants selected among ten stimuli that would be used during the sorting task. In the paired stimulus condition, the researcher could only use the top three stimuli identified from the paired stimulus preference assessment, and in the IMRA condition the researcher, who was blind to the results of the paired stimulus preference assessment, could use any of the ten stimuli. The results of the study showed equivalent rates of sorting across the two conditions, but using IMRA, as opposed to the paired stimulus preference assessment, was more efficient with respect to time spent conducting the formal preference assessment. Leaf and colleagues (2016c) extended the findings of Leaf et al. (2015) by comparing the paired stimulus preference assessment to IMRA when teaching expressive labels with two children diagnosed with ASD. The methods employed were identical to those of Leaf et al. (2015) utilized; however, Leaf et al. (2016c) evaluated the two conditions with respect to the acquisition of a new skill (i.e., expressive labels). The results were similar to Leaf et al.'s (2015) study in that the participants

acquired the skills in both conditions, but the IMRA condition was again more efficient with respect to time spent in the formal assessment.

Reinforcement systems. Once potentially reinforcing events have been identified for use during intervention, reinforcement systems (e.g., token system) are typically developed to help improve pro-social behavior. Within a progressive approach, the behavior analyst is not limited to providing reinforcement on a predetermined schedule (e.g., FR1, VR3) or for predetermined behaviors (e.g., always provide access to candy following X response). Instead, the interventionist has the discretion to make in-the-moment adjustments to the reinforcement schedule as needed (e.g., when it is determined that a high level of response effort is required due to transient circumstances). In one recent example of a responsive, flexible reinforcement system, Leaf and colleagues (2017) used a level reinforcement system as part of a behaviorally based social skills group for children diagnosed with ASD. Within this level system, the children could move up and down within and across various levels, and each level represented a different contingency (e.g., the top indicated access to a treasure chest with various toys, the bottom indicated a brief time out from the activity). During the social skills group, the interventionists had the flexibility to provide reinforcement (i.e., movement up) and punishment (i.e., movement down) based upon his or her in-the-moment assessment of child performance. Thus, the rate of reinforcement was not predetermined and, instead, was responsive to child performance on an individual basis. Overall, the results of the randomized control trial showed significant gains in the social domain across a variety of standardized assessments for all participants.

Discrete trial teaching. One of the most commonly implemented behavioral techniques for individuals diagnosed with ASD is discrete trial training (DTT). The common implementation of DTT has led to descriptions and best practice recommendations of how to implement DTT (e.g., Grow and LeBlanc 2013; Leaf et al. 2016a). Some recommendations that align closer to a conventional approach have included only

using counterbalancing and an array of three stimuli with teaching receptive labels, only using simplified instructions (e.g., saying “ball” as opposed to “find the ball”) and not varying the instruction from trial to trial (Grow and LeBlanc 2013). These recommendations align with a conventional approach as they are followed without assessing and responding to a particular child, and instead the interventionist is responsive to a set of rules. Leaf et al. (2016a) outlined how this conventional approach contrasts with a progressive approach to DTT. Across the guidelines provided for a progressive approach to DTT, a general theme emerged. Each guideline described assessing the conditions under which an interventionist should or should not alter certain variables such as complexity of language, stimulus presentation, and selection of prompting systems. Ultimately, within a progressive approach to DTT, interventionists are not bound by inalterable rules and make in-the-moment assessments to determine what, if any, changes should be made from trial to trial, session to session, and child to child.

In a recent study, Leaf et al. (in press) compared elements of a conventional to a progressive approach to DTT for the five participants diagnosed with ASD. Specifically, Leaf and colleagues evaluated the recommendation to counterbalance the stimulus array when teaching receptive labels by comparing it to two conditions, one in which the stimuli were not moved across trials and another in which the interventionist had the flexibility to move or not move the stimuli across trials. The results were idiosyncratic across the five participants and stimulus sets. That is, there was no substantial difference when stimulus rotation was prescribed to move or not move on every trial. While this study had limitations and further research is needed, these preliminary findings show the importance of evaluating claims of best practice recommendations.

Prompting. One component which is usually a commonly included component within DTT is the provision of prompts. Within a conventional approach, a protocol typically controls when the interventionist prompts, fades a prompt, and what prompts to provide. A more progressive approach, on the other hand, utilizes what has been

described as flexible prompt fading (FPF). This prompting system relies on in-the-moment assessment to guide interventionist's selection of prompts and prompt fading. Instead of strict rules, FPF is guided by in-the-moment assessment and a goal to maintain the child's success rate at around 80% of opportunities.

Several studies have evaluated the use of FPF to teach various skills for individuals diagnosed with ASD. For instance, Soluaga and colleagues (2008) compared FPF to a constant time delay prompt to teach a variety of receptive labels to five children diagnosed with ASD. The results of a parallel treatments design showed that both prompting procedures were effective at teaching the various skills, but FPF was more efficient. Leaf et al. (2014) compared FPF to an error correction procedure to teach expressive labels to four children diagnosed with ASD. The results of a parallel treatments design again showed that both procedures were effective and FPF was more efficient. More recently, Leaf and colleagues (2016b) compared FPF to most-to-least prompting for teaching expressive labeling to four children diagnosed with ASD. Once again, both procedures were effective, but FPF was more efficient for three out of the four participants. Furthermore, FPF resulted in higher rates of independent correct responding during teaching. Taken together, these evaluations of a more progressive approach to prompting show that responding to child behavior, instead of to a protocol, can be effective and more efficient than a protocol-driven conventional approach.

Data collection. A cornerstone of any science is data-based decisions, and ABA is no exception. Specifically, ABA relies on objective data to make decisions about progress during treatment and to continue or discontinue certain procedures. Conventionally, data is taken continuously (e.g., frequency counts), discontinuously (e.g., time interval), or some combination of the two for all behavior in all environments. In a progressive approach to ABA, data is critical; however, the type of data system varies based upon several variables such as the task, frequency of the behavior, duration of the behavior, how informative the data is for demonstrating progress or informing

changes to the intervention, and the extent to which data collection might interfere with learning opportunities. Thus, continuous measurement may be indicated in some instances, while discontinuous measurement is indicated in other instances, and, at times, estimation data (Taubman et al. 2013) may be appropriate. Therefore, one type of measurement system is not used exclusively over others, unless that is what is required for the child and staff.

Global outcomes. To date, there have been two comprehensive studies that have evaluated a progressive approach to ASD intervention. Leaf and colleagues (2011) provided a programmatic description (i.e., an observational study without the use of an experimental design) of a clinic-based progressive approach to ASD intervention for individuals diagnosed with ASD. This description included an analysis of data for 64 individuals diagnosed with ASD who received services in 4 clinics based in the United States, Hong Kong, Australia, and the United Kingdom. The results of the analysis showed that 39% of the participants reached "best outcome" based on the criteria Lovaas (1987) outlined. Furthermore, an additional 31% would be considered best outcome by a revised definition (i.e., the same criterion used in Lovaas (1987) with the caveat that clients could receive minimal school support). Taken together, 70% of the clients served across these clinics providing a progressive approach to ASD intervention reached best outcome measures.

More recently Leaf et al. (2016) used a progressive approach to ASD intervention as part of a 16-week behaviorally based social skills group intervention. The interventionists in this group implemented a range of techniques (e.g., discrete trial teaching, shaping, cool vs. not cool, role play). The curriculum was not prespecified, was based upon several factors (e.g., child deficits, parent's desires of what to teach their child, or age typical social behaviors), and was individualized. The results of a randomized control trial showed that the intervention was successful at achieving significant gains in social behavior that were maintained over time. These two evaluations provide a small sample of progressive approaches to ASD intervention that result in

significant, meaningful gains, for individuals with diagnosed ASD.

Future Directions

Despite the recent increase in research and descriptions of a progressive approach to ASD intervention, more research is needed. First, future researchers should evaluate a progressive approach with a wider body of techniques and approaches to treatment (e.g., functional analyses or using consumer-friendly language as opposed to technical jargon). Second, researchers should continue to compare elements of a progressive approach to other approaches to identify the most efficacious techniques. Third, researchers should evaluate training professionals in a progressive approach. Fourth, researchers and professionals should continue to identify the characteristics of a progressive approach. Finally, research needs to be conducted across a wider variety of professionals and research labs. Continuing these lines of research would extend the knowledge of a progressive approach to ABA and ASD intervention and may lead to better outcomes for individuals diagnosed with ASD.

Nature of Projective Tests

Projective tests, also commonly called projective techniques, encompass a class of psychological measures characterized by two key features. First, they present a relatively unstructured or ambiguous stimulus (e.g., an inkblot) to which a person responds. Second, they allow for great latitude in the person’s response. Projective tests are contrasted with objective or structured measures which present a simple, clear stimulus (e.g., a statement such as “I often feel strange”) accompanied by a selected-response method of responding (e.g., Yes/No).

The rationale underlying use of a projective technique is the “projective hypothesis” which asserts that when faced with an ambiguous stimulus and given great freedom in responding, an individual’s personality dynamics will determine the response; and, therefore, the projective technique may reveal dynamics not detected by objective measures.

Extent of Use

Surveys show that projective techniques are very widely used in clinical assessment. This has been true over a long period of time and across many subfields including clinical, counseling, school, and forensic psychology, and neuropsychology (Hogan 2015). In several surveys identifying the most widely used psychological tests, various projective techniques usually garner four or five of the top ten spots. Doctoral work in clinical psychology also typically requires training in use of projective techniques such as the Rorschach. Some uses of projective techniques involve formal scoring, as described later. However, some

uses are informal, serving an “ice breaker” function: presentation of a nonthreatening stimulus to facilitate initial discussion and establishing rapport with a client without formal scoring.

Indicators for Use of Projective Techniques

Certain circumstances may suggest that use of projective techniques is particularly appropriate. First, most projective techniques require little or no literacy skills and, therefore, may be useful with persons of low educational level. Second, projective techniques, with their ambiguous stimuli, are less susceptible to faking (good or bad) than more objective measures. Third, projective techniques may be especially useful for hypothesis generation when the clinician has little initial notion regarding the source of a person’s difficulty.

The following sections describe the most widely used projective techniques, including basic description of the techniques and their typical applications.

Rorschach

The Rorschach Inkblot Test (RIT) is clearly the most widely used projective technique. The standard version of the RIT consists of 10 bilaterally symmetrical inkblots, five with mixtures of black and various shades of gray, two with black and gray with splotches of red, and three with mixtures of pastels. Each inkblot appears in the middle of a rigid piece of cardboard measuring about 6×9 inches.

Based on appearance of inkblots in the popular media, some people may think that administration and interpretation of the inkblots is a simple, intuitive matter: Show an inkblot, get a response, and, presto, you know a person’s innermost thoughts and feelings. That is certainly not the case with formal use of the Rorschach in contemporary clinical practice. Following Hermann Rorschach’s (1921) publication of these inkblots, several systems for administering, scoring, and

interpreting the RIT emerged. In the early 1970s, John Exner began development of the Comprehensive System (CS) for administration and scoring the RIT, selecting what he judged the best and most promising features of previous systems. The CS is now the industry standard for formal use of the RIT. Exner’s three volumes (Exner 2003; Exner and Erdberg 2005; Exner and Weiner 1995) serve, in effect, as the test manual for the RIT-CS.

Administration of the RIT-CS involves two phases. First, in the response phase, the examiner hands one of the inkblot cards to the client and asks “What might this be?” If necessary, the examiner encourages responses with statements such as “Most people see more than one thing.” The examiner records responses verbatim, as nearly as feasible. The examiner presents each card in turn with the latter directions. Then, in the inquiry phase, the examiner reintroduces each card, reminds the client of his or her response(s), and asks for elaboration on the responses, saying, for example, “Show me where you saw ____.” The examiner also records these responses verbatim.

Scoring the RIT-CS involves, first, application of an elaborate set of codes to the responses and, second, conversion of these codes into a host of ratios, percentages, and derivations. Codes occur in several major categories, for example, location, form quality, and determinants. The codes within the location category tell, for example, whether the response was to the entire blot (W), a common detail (D), an unusual detail (Dd), or to a space (S) rather than to the inkblot itself. Determinants deal with what features of the blot determined the response, for example, an animal figure, human figure, or movement. The host of coded responses are then converted into a variety of derivations (e.g., ideation, affect) and “constellations” (e.g., depression index, coping deficit index), eventuating in the Structural Summary, which serves as the primary basis for interpretation in the RIT-CS. Interpreting the Structural Summary requires advanced training. Computer programs aid in development of the Structural Summary after the initial coding, and computer-generated narrative reports are also available to aid interpretation.

Following Exner's death in 2006, several of his understudies, plus others, developed the Rorschach Performance Assessment System (R-PAS). This system is similar to but not identical to Exner's CS. R-PAS maintains a very active website (r-pas.org), program of research, and series of training opportunities. R-PAS now rivals CS in usage (Gurley 2017). See also Groth-Marnat and Wright (2016) and Weiner and Greene (2017) for comparisons of CS and R-PAS. Mihura and Meyer (2018) provide examples of the use of R-PAS in a variety of applications.

More so than for other categories of psychological assessments, exceptional controversy surrounds the use of projective techniques, with particularly vigorous debate centered on the Rorschach. Some authorities believe even the better known projectives, to say nothing of clearly discredited techniques, generally lack acceptable psychometric quality. Other authorities maintain that selected projective techniques, properly administered and interpreted, compare favorably with widely used measures of cognitive ability and objective measures of personality traits. See Krishnamurthy et al. (2013) for a summary of the arguments pro and con. Meta-analyses of validity studies for the RIT by Mihura et al. (2013) and Wood et al. (2015) are particularly helpful in showing that previously contending factions now agree that at least some Rorschach scores have respectable validity.

Thematic Apperception Test and Other Story-Telling Techniques

Another widely used projective technique is the *Thematic Apperception Test* (TAT). The TAT consists of 30 cards, 9 × 12 inches, each containing a photo deliberately selected to present an ambiguous situation; one card is entirely blank. Directions vary but generally ask the respondent to tell a story, including what is happening, what led up to the situation, and what the outcome may be. Not all cards are used with all respondents; some are meant only for boys, others only for men, others for girls, and others for women. Some examiners may select their own subsets of

cards. In clinical practice, clients usually respond orally. Research applications, with literate respondents, often employ a written response.

The TAT was developed by Murray (1943) to help measure his personality theory based on sets of psychological needs (e.g., affiliation, achievement) and presses (environmental forces). In contemporary practice, the TAT has numerous scoring systems (Jenkins 2008; Teglasi 2010). Typically, the systems use only 8–10 of the 30 cards, with exact selections varying among the systems. Bellak's system (Bellak and Abrams 1997) is one of the more widely cited. The diversity of systems militates against the development of research-based generalizations for the TAT, likely explaining the decline in its usage.

The TAT has two offshoots: The *Children's Apperception Test* (CAT) and *Senior Apperception Test* (SAT, not to be confused with the SAT used for college admissions), both similar to the TAT in purpose and general structure but using pictures more appropriate for their respective target groups. Bellak's work covers the CAT and SAT as well as the TAT.

Research with the TAT shows that it has some limited utility in measuring a few of the traits originally postulated by Murray, for example, achievement motivation, need for affiliation, and aggression. However, its use in ordinary clinical practice has declined in recent years primarily due to unsystematic administration and scoring procedures and a lack of rigorous psychometric work (Dana 1996).

Another story-telling projective technique is the *Roberts-2* (Roberts and Gruber 2005), a revision of the *Roberts Apperception Test for Children*, intended for ages 6–18. Like the prototype TAT, the test presents a series of pictures and asks the respondent to create a story with a beginning, middle, and end, and with specific reference to feelings evoked by the picture. The test aims to measure what it refers to as social understanding. It applies a set of codes for responses in a manner similar to that described earlier for the RIT-CS. Application of the codes results in 18 Developmental/Adaptive scales (e.g., Limit Setting, Constructive Resolution) and 10 Clinical scales (e.g., Aggression, Maladaptive Outcome). Although

the manual claims the test is not a projective technique, it clearly is projective by any conventional definition. An accompanying “casebook” provides one case of a child with autism and one with Asperger’s disorder, as well as a host of other types of cases. However, the manual presents no normative information for autism or other developmental disorders. The manual provides data for a general standardization sample and for a sample of undifferentiated referred clinical cases. Normative information for groups of cases such as those included in the casebook would enhance usefulness of the *Roberts-2*, particularly for research on social understanding in children with autistic spectrum disorders.

Sentence Completion Tests

The sentence completion technique presents the respondent with a few words in a sentence stem (e.g., I feel . . . or Most people . . .) and the respondent completes the sentence in his or her own words. The sentence completion technique is the only widely used projective technique that requires writing; it, therefore, depends on some degree of literacy and is not typically used below the high school level.

Numerous specific sentence completion tests (SCTs) are available; Holaday et al. (2000) described 15 SCTs. The most widely used is *Rotter’s Incomplete Sentences Blank* (RISB; Rotter et al. 1992). It consists of 40 incomplete sentences. There are three forms: high school, college, and adult. RISB attempts to measure only one psychological construct: maladjustment. The RISB manual provides specific guidance for rating each completed sentence on a seven-point scale for the degree of adjustment/maladjustment reflected in the wording. These ratings on individual sentences then sum to a total maladjustment score.

Torstrick et al. (2015) and Weis et al. (2008) provided favorable evidence about the validity of the RISB as a measure of maladjustment. Because sentence completion techniques require both reading, albeit minimal, and writing, they are not typically used with children.

Human Figure Drawings

Human figure drawings (HFD), also known as draw-a-person (DAP) tests, encompass a generalized technique as well as several specific tests. As a general technique, the procedure usually calls for the respondent, first, to “draw a picture of yourself,” followed by “draw a picture of a person of the opposite sex,” and may also include “draw a picture of your mother (or some other named person).”

Many clinicians “score” the drawings in only the most impressionistic manner. Alternatively, a variety of specific scoring systems have been proposed. The earliest use of the procedure aimed to provide a nonverbal measure of intelligence and the method still experiences some use for that purpose (Naglieri 1988), although it is much more frequently used as a projective measure of personality. Machover (1949) offered a widely cited but largely discredited system for interpreting human figure drawings. Naglieri et al. (1991) developed the *Draw-a-Person: Screening Procedure for Emotional Disturbance* (DAP: SPED) as an objectively scored, psychometrically sound version of the technique. The DAP: SPED manual provides comparative data for several special education samples in the age range 10–12 years but with no apparent representation of autistic syndrome disorder (ASD) cases.

Other drawing-based techniques include the *House-Tree-Person* test, with directions calling for, as suggested by the title, drawing a house, tree, and person; and the *Kinetic Family Drawing*, with directions calling for drawing a picture of a family doing something.

Despite the widespread use of human figure drawings in clinical practice, they have not fared well in psychometric research (Sattler 2014; Weiner and Greene 2017). At best, they may reveal some aspects of gross ideational or emotional aberration, and they may serve the purpose of hypothesis generation for later follow-up or as an ice-breaker.

Bender Visual-Motor Gestalt Test

The *Bender Visual-Motor Gestalt Test-II* (Brannigan and Decker 2003), usually referred to simply as the

Bender, consists of a series of geometric configurations presented on individual cards (e.g., two intersecting wavy lines). Administration proceeds in two phases: copy and recall. First, the examiner presents each card in turn and asks the client to copy the figure. After all cards have been presented, the examiner asks the client to draw as many of the designs as the client can recall. Each response is scored on a five-point scale from no-resemblance to near-perfect resemblance to the original figure.

The Bender's original purpose and most frequent uses are for neuropsychological evaluation. However, some clinicians use it as a projective technique, scoring responses for "indicators" of ideational aberration or emotional disturbance.

Clinical Uses of Projective Techniques for Autism Spectrum Disorders

Psychological tests receive use for initial diagnosis of a condition, treatment planning, follow-up evaluation of treatment outcomes, and for research to better understand a condition. Projective techniques appear to have little relevance for initial diagnosis for ASD cases. Initial diagnosis typically occurs at an age below the functional range for projective techniques. Furthermore, several well-established objective tests and methods exist for evaluating communication skills and social relationships relevant to autism spectrum disorders (Bishop et al. 2008; Ibanez et al. 2014; Lord et al. 2014). Projective techniques may be useful at older ages for treatment planning and follow-up evaluation, especially for comorbid conditions. However, any clinical use of projective measures with this population will require careful attention to the developmental level of the individual being assessed, and, in the absence of appropriate normative data for ASD samples, interpretations will necessarily be quite tentative.

Projective techniques may be of use for a variety of research purposes to develop broader understanding of the emotional and social lives of individuals with autism spectrum disorders. To date, uses of projective techniques with ASD cases have been characterized by isolated studies

with quite limited samples. However, some promising lines of research have developed. Emotion researchers have noted the importance of self-report information in understanding the emotional experiences of children and adolescents (Zeman et al. 2007), and projective measures can help elicit such information. An example with high-functioning ASD is found in the work of Bauminger et al. (2004), who studied loneliness, perceptions of friendships, and understanding of social interactions in school-aged children using, among other measures, thematic picture-based procedures with open-ended questioning. The Friendship Picture Recognition Interview (see Bauminger et al. 2004), described by the authors as a projective test, consists of a single color drawing of two children engaged in a close social interaction. Examiners ask all children a set of three questions and, depending on response to the third question, some children are also asked a fourth. The authors provide the procedure for scoring responses along with some information about interrater agreement. Informative results have been obtained from this and the group's other picture-based measures, but there is no indication in the literature of use of the measures by other researchers. Kenworthy (2010) provides another example of the use of the story-telling method, specifically the *Roberts-2*, in this instance to track changes in social perception in an ASD case.

In a study on theory of mind, Beaumont and Newcombe (2006) note that important information about high-functioning individuals' understanding of others' mental states can be obtained from measures that include spontaneous speech and narratives. That is, open-ended measures can add to the information obtained from more structured, objective measures. They included an "open-ended TAT narrative task" in a comparison of 20 individuals with high-functioning autism or Asperger's disorder and 20 controls matched on IQ, sex, and age. Six of Murray's TAT cards were used and the directions given to participants were the same as specified in the manual. Responses were not coded for traditional personality themes but for theory of mind constructs, using categories based on previous narrative studies with children by theory of mind researchers. Hypothesized differences were

found between the ASD and control groups on “mental state causal statements.” The results add interesting information about specific aspects of mental state understanding in this group.

Projective measures might also have utility for research on emotions and social perceptions in lower-functioning adolescents and adults. Dykens et al. (2007) have called for research into the rich internal lives of individuals with intellectual disabilities (ID) and suggested “semi-projective” measures as a way to obtain self-reports from these individuals. They recently used sentence completion and three-wishes tasks to obtain information about emotions and aspirations from individuals with ID associated with genetic syndromes. Content analysis was utilized and high intraclass correlations reported. The measures might prove useful for similar purposes with individuals with ASD and ID.

Several studies have employed the Rorschach with ASD cases, in all instances using Exner’s CS to report scores. Dykens et al. (1991) used the Rorschach to examine thought disorder in 11 high-functioning ASD cases and compared results with the CS schizophrenia reference norms. Ghaziuddin et al. (1995) also used the CS to compare 12 Asperger syndrome cases with 8 high-functioning autism cases and found differences on a few of the structural summary variables. It should be noted that Exner’s structural summary provides a score labeled ALOG, which originally stood for Autistic Logic but was later renamed Inappropriate Logic, although the acronym ALOG was retained. One should not assume that ALOG relates to autism in any special way.

Holaday et al. (2001) tested hypothesized differences in Rorschach protocols between 24 boys with Asperger’s disorder, 24 with “other emotional or behavioral disorders,” and the normative data. Several expected differences were found on social variables and, importantly, the authors provided group means from both of their sample groups for all of the variables in Exner’s normative tables, with a stated goal of improving the Rorschach’s potential utility for difficult differential diagnosis between Asperger’s and other conditions.

Yalof (2006) found several scores in Exner’s CS for the Rorschach useful in a detailed case study of a difficult differential diagnosis related

to nonverbal learning disability and Asperger’s syndrome. Yalof also reported using figure drawings and the TAT in this case study but appeared to use these two measures only impressionistically rather than in terms of formal scoring.

Several reports have considered the use of human figure drawings with ASD cases. Klin et al. (2005) suggested that informal use of drawings may have some use in understanding an autistic child’s thinking. Lee and Hobson (2006) obtained intriguing differences between 14 autistic cases and 14 learning disability cases matched on age and verbal ability in certain characteristics of human figure drawings but not on house drawings. Lim and Slaughter (2008) also used human figure, house, and tree drawings to compare 29 Asperger’s syndrome cases with 28 typically developing children, matched on gender, age, and nonverbal IQ, and found differences in the human figures but not on the house or tree drawings.

Roman (2005) proposed a free-play based projective technique (the *Projective Kit for Early Childhood*) for children aged 6 months to 4 years, suggesting that it might help “... to identify milestones in autistic vs. nonautistic mechanisms of relationship to the world through the children’s play” (Roman et al. 2011, p. 249). To date, this relatively new technique has not garnered much research attention.

Research literature on use of projective techniques with autistic syndrome disorder cases is not large but it is growing and it has suggested some possibly fruitful areas for further development. There is a particular need for normative studies of projective indexes with sizable groups of ASD cases. Such information may provide a useful adjunct to the currently established diagnostic instruments. Studies reviewed here also suggest that projectives may help to expand our understanding of the cognitive and social interaction features of ASD.

Description

Comment

This is only a partial list of the projective instruments that might be administered, and projectives are only one kind of personality test which might be utilized in psychological evaluation (Adams and Culbertson 2009). And while the projective tests are described separately here, they are commonly given along with other psychological instruments to describe cognitive and processing skills as well as social and emotional functioning. In addition, psychological testing is commonly supplemented by a good deal of other information, including different kinds of rating scales, in order to make diagnostic as well as descriptive comments. The projective tests are given to provide information to professionals and parents regarding the “inner workings” of complex patients, and to help them make diagnoses and

Projective Tests

► [Projective Tests of Personality](#)

design interventions in complicated cases, including autism. The actual diagnosis of Autism Spectrum Disorder (ASD) is made according to strict historical and behavioral criteria described in the Diagnostic and Statistical Manual of Mental Disorders (DSM). All the same, projective testing can be useful in supporting the diagnosis of autism or exploring alternative or additional diagnoses. Regardless of diagnosis, projective testing can be helpful in describing individual functioning, thereby enhancing the process of making recommendations for any specific client, including those with autism.

Overview

There are times when parents and professionals ask “Why?” a child is responding as they do or “What?” is going on. Beyond asking for a label to be applied to their youngster, they are asking for a comprehensive description of their functioning and recommendations to make things better. In these cases, projectives may enhance the overall evaluation of an individual with autism.

“Projective tests” refer to a range of psychological instruments focused on the assessment of personality and personal functioning. There is no real “right” answer. Instead, it is anticipated that the patients will “project” their own thoughts and feelings about themselves and life onto the external world. These projective tasks can include describing the inner life of an imaginary individual, completing a variety of sentences about life, telling stories about common and uncommon situations, and saying what amorphous inkblots look like.

Although the focus of interpretation of the tests is often on personality issues, the projective tests provide opportunities to assess a range of interacting and overlapping cognitive/processing and social/emotional functions. It is anticipated that the answers on projectives will reveal something about the unique style and perspective of each client. While in general practice projective tests are often undertaken to help clarify psychiatric diagnosis, in the context of autism, they are more often performed to describe psychological and interpersonal

functioning and to help individualize understanding and therefore intervention.

Projective assessment can enrich the evaluation of an individual with autism by focusing on the challenges they face from their own point of view and by helping professionals to be specific about intervention strategies. This allows mental health specialists to move beyond “making referrals” to professionals or even treatments; it helps parents and professionals to interact with patients and intervene around difficulties in a more fine-tuned way.

While there is no set agenda or inquiry, questions about patients might include the following: Do they function better in some situations than others? What kinds of situations or stressors seem to throw them? Is the problem more with how they understand things or with how they regulate emotion? What should professionals be aware of as they try to intervene in clinical and treatment settings? What can caretakers do to support and teach them so that they can be more adaptive on an ongoing basis, including at home and in school? Or, does the data suggest some diagnosis in addition to (or other than) autism which the treatment team should be aware of?

Projective testing can provide insights around individuals with autism which can help caretakers care for them better.

Instruments

The projective instruments utilized can include the full range of projective tests used with children, adolescents, and adults. What is appropriate will depend on a number of developmental features, including the intellectual level and language facility of any patient. Because psychological evaluation around autism more commonly involves children and adolescents than adults, the following discussion reflects this fact. While the use of projective testing with individuals with possible autism is not routine, when it is done, it frequently involves a battery of tests that fairly systematically assesses different ways/levels of organizing (structuring) information as they interact with different kinds of input (visual and

auditory) and output (motor and verbal). While the psychologist is interested in how the patient conceptualizes their social relationships and experiences their emotional life, he or she is also interested in the cognitive and processing infrastructure (underpinnings) which facilitates or impedes adaptive and appropriate social and emotional functioning (Jura and Humphrey 2017). Particularly in the case of developmental disabilities, the psychologist considers whether responding on a task or item is developmentally appropriate, immature, or deviant. The psychologist assesses whether any disruption is associated with intellectual challenge, skills deficit, or personal difference. The range of tasks presented involves varying demands on graphic ability (including the ability to draw a person or perhaps write a response), but particularly language facility; this can include not only receptive and expressive functions in oral and written form but also pragmatic communication skills as they are depicted or evident during testing. In analyzing responding, the psychologist tries to parse out the various intellectual, processing, social, and emotional factors that might have influenced a client's unusual test protocol. In this analysis, the psychologist remains aware of not only client responding but also test demands. Further, the psychologist tracks client behavior as well as actual answers. Some tests/items go more smoothly than others. This gives the psychologist an opportunity to observe the client's response to facility in some situations, in contrast to cognitive or social challenge in others, and perhaps ensuing frustration. Below, the tests will be described in the order in which they might be administered (basically from most to least structured, with increasing ambiguity and leeway over the session/s). Included in the descriptions are comments about the test characteristics and their utility. While this battery of tests is most likely to be administered during the assessment of autism, the same instruments might be given to an individual who has been diagnosed with autism, but professionals feel the situation is particularly complex and in need of clarification. The interpretation of any projective results is based on the context of the assessment and any guidelines associated with each

instrument, as well as the clinical experience of the examining psychologist. Based on the referral issues and goals of the assessment, the examiner may vary the test administration and therefore the analysis, in order to enhance the usefulness of the evaluation as a whole to any particular patient. What follows is a list of the types of projective instruments most often used in exploring autism.

Figure Drawings

On the *DAP*, the examiner asks the client to "Draw a person." There are variations on this direction which allow the rendering to be scored for general intellectual maturity ("Draw a picture of a man, and the very best picture you can.": *DAM*). There are other variations which potentially involve members of the family ("Draw a family": *DAF*) or people and objects ("Draw a house, a tree, and a person": *HTP*). The advantage of the simple *DAP* is that subsequent to asking the patient to draw the person, the examiner can then ask a number of questions about the individual's behavior, thoughts, and emotions, "as if" this were a real person. The psychologist subsequently notes whether the figure is well drawn or not, and possible cognitive and/or psychological reasons for a limited or disorganized presentation. The examiner also notes any personal themes that are hinted at in comments about how the figure might act, think, or feel and whether the client has the general capacity to imagine the internal life of another person.

Sentence Completion

On the *SCT*, the examiner asks the patient to complete a series of incomplete sentences. There are a number of variations on this, with different sets of sentences provided for different genders and ages. The client can be asked to hear or read each sentence (e.g., asking about family, fears, peers, or dreams) and then to respond by saying or writing their response. The administration allows for adjustments around level of development and purpose of evaluation and can provide opportunities for both oral and written language samples. The products can be assessed for formal expressive competence and thought coherence, as well as personal concerns. The examiner most

commonly reviews the responses for patterns of responding which suggest the personal approach of the client toward the people around them (including parents and friends), as well as the particular hopes or conflicts which are evident around ordinary life activities.

Thematic Approaches

On the *TAT*, the psychologist asks the patient to tell stories to black-and-white pictures, commonly of people, and usually in ordinary settings. Designed for adults and children, the TAT can be given to youngsters starting at about the age of 7–8 years, depending on a number of developmental and cultural factors. Often in the case of the populations addressed here, five to ten pictures (out of set of 31) are presented. The pictures may depict children or adults by themselves or in groups, perhaps in a rural scene or within an ordinary house. Some situations are more ambiguous or fanciful. Stories are assessed for cognitive factors such as coherence, as well as social/emotional concerns. The themes are seen in basically dynamic (psychological/personality) terms. A less arousing and challenging test has been designed for children: the Children's Apperception Test. It can involve ten scenes with animals (*CAT/CAT-A*) or people (*CAT-H*). Traditionally, the approach has been seen as based on psychoanalytic theory (a theory of psychological development focusing on characteristic themes at different ages/stages). Currently, the analysis is usually based on more generic psychodynamic understandings (general themes of psychological/interpersonal functioning). It is the premise of the thematic instruments that the patient will project their own views and concerns onto the scenes and individuals depicted. For example, the scenes might show a child with a musical instrument or might suggest a parent disciplining a child. The client has a wide variety of choices regarding how they see these situations and tell stories about them. Thematic material presents opportunities for the psychologist to identify patterns of perception and relating which might characterize the client in real life. While the CAT and TAT can be looked at systematically in order to understand the patient's approach, they are not (strictly speaking or very

commonly) scored. However, another thematic test can be scored, the Roberts test/s (*RATC, Roberts-2*). In fact, because of its methodical procedures, it is denied the Roberts-2 is a "projective test" (e.g., Parolin et al. 2019). It is noted the test uses the client's expressive language as a way of measuring the child's social cognitive skills and is standardized on nonreferred children. All the same, because it involves telling stories which reveal aspects of the client's social perception and emotional approach, it is included here. Currently on the Roberts-2, 16 pictures (with parallel versions, depicting Hispanic, White, or Black characters) are presented; all pictures in a set must be provided because of scoring issues. These are the thematic instruments which are most likely to be seen in the evaluation of a range of clients, including those with possible autism, although there are other tests available which might potentially be utilized.

Unstructured Material

On the *Rorschach*, the examiner asks the patient to view ten simple to complex inkblot designs; they are commonly black but sometimes involve red or pastel colors. While this instrument theoretically can be given to younger children (down to 5 years), it is typically administered to individuals about 6–7 years and up. Because of the potential for scoring, it is given according to strict directions and rules, and responses are recorded verbatim for later scoring and analysis. On each blot, the examiner asks the client what the inkblots look like to them ("What might this be?"). This is a test of perception, where the patient first gives one to several responses to each blot and then is asked to explain or justify their percept. The responses can subsequently be scored for factors based on appropriateness of the response (goodness of fit of percept to blot) and the determinants of the percept (e.g., the shape or color of the design), as well as other features of the response (including thought process or subject matter). Different scoring systems have been utilized over the years. According to the more current Exner comprehensive system, the pattern of responding is assessed according to formal response characteristics, importantly providing

information around cognitive integration (the ability to pull together information) as well as social and emotional functioning. While the Rorschach can be scored, some psychologists under some circumstances may interpret the client's responding without formally scoring the performance, but with knowledge of what scoring might mean to the individual's psychological functioning. From the Rorschach, information can be provided regarding the client's reality testing as well as accessibility to human experience, including relationships and emotions. Data can also be provided around the subject's ability to deal with stress and their capacity for disorganization. For example, the psychologist commonly looks at the pattern of responding to learn how much structure the client requires to see the world as others do or to get a feel for how susceptible the client is to dysphoric affect (anxiety/depression).

Interpretation

While comments might be made about the significance of responding on individual tests, the test analysis is usually based on the battery as a whole.

Pattern

It is the assumption of the psychologist that the client's responding on these tasks reflects the ways they habitually perceive situations and organize their experience and, therefore, suggests their typical thoughts, concerns, and approach. No one instrument, or response on any instrument, is definitive. It is the pattern of responding which suggests the way a patient is apt to handle situations and conflicts and to cope in life. Further, the pattern can be understood in cognitive/processing as well as social/emotional terms and levels, with implications for adaptive functioning. For example, the instruments used in a battery of tests can require increasing verbal and conceptual skills and thus have increasing potential for revealing how the client understands their experience. In this context, a patient may have the skill or motivation to provide the short response required on the DAP or SCT, but not to tell or write a more extensive response to the TAT. Further, the SCT may provide only a glimpse of the concerns reflected in more elaborate form on the TAT or

on the Rorschach. When the psychologist considers both cognitive/processing and social/emotional reasons for disruption, projective testing can help parents and professionals to better understand "why" the child proceeds as they do in life and help the treatment team to be more specific about the kinds of strategies which might benefit the patient.

Utility

Even when the projective instruments are scored, there is a large discrepancy between the information to be gleaned and any diagnosis to be made. And regardless of scoring, interpretation of projective tests can remain largely subjective. Further, most diagnoses are made based on psychiatric history and current presentation. Projective tests can only be viewed as consistent with the diagnoses being considered, and not as definitive of any particular diagnosis. Projectives provide only one (or several) data point/s among many in the process of assessing any child, adolescent, or adult. This is particularly true in the case of autism, where the diagnosis is made according to criteria falling within specific spheres and is based on history and behavior. All the same, when the patient cannot speculate about what the DAP figure is doing, thinking, or feeling; has difficulty telling a coherent story on the TAT/CAT which includes human motivations or interpersonal interactions; and struggles to identify ambiguous inkblot designs on the Rorschach in the most ordinary ways, one has a richer understanding of how the client approaches life and how challenging he or she finds it. To a certain extent, projective testing can be an assessment of severity – the performance suggests to what extent the client has difficulty making sense of their experience and therefore responding appropriately. Taken together, the test instruments can reflect difficulties with information processing which are seen on intellectual tasks (perhaps tasks which require creating a cartoon narrative or assembling a schematic puzzle) and also on projective instruments (which challenge the client to "make meaning" of a variety of scenes or blots). Together, the projective and cognitive tests can provide a fair assessment of the individual's

ability to understand their experience and deal with the passing social scene. They can help to identify specific difficulties that suggest “what” to do and target interventions in the context of the treatment plan.

Appropriateness

It needs to be noted that this discussion about the use of projective tests in assessing autism is being undertaken at a time when there are doubts about the validity of projective tests in the diagnosis and evaluation of psychological problems and psychiatric illness at all. In this context, a distinction needs to be made between clinical description and clinical diagnosis. Clinical diagnosis according to the Diagnostic and Statistical Manual of Mental Disorders (DSM) tends to be made based on a constellation of criteria, noted in history and presentation. In the case of some diagnoses, while some intellectual or achievement testing might be relevant (and rating scales might be helpful), even in the case of more emotional disorders, projective testing tends not to be necessary. Clinical description is another matter. While not necessary, projectives might be very relevant in assessing affect, thinking, and relationships in a variety of diagnostic contexts. This can include autism, although the situation is complex. In the case of a developmental disorder like autism, it is legitimate to ask whether it is appropriate to use projective tests which have been developed, understood, and in some cases normed, based on neurotypical populations. It needs to be emphasized that projectives may not be relevant/necessary to making the diagnosis of autism, but they may be very useful in assessing the autistic individual, so long as developmental issues are taken into account. In diagnosing and evaluating autism, prudent practice can involve a range of specific assessments (e.g., adaptive functioning or communication skills), which further help to spell out the affected individual’s strengths and weaknesses and to identify areas for intervention. As an extension of this evaluative and descriptive process, projective assessment can help to clarify the individual’s functional profile, either as part of an original assessment or as part of a subsequent evaluation. To effectively

intervene, it is not sufficient to label the patient as “autistic.” The individual is not simply autistic – he or she may manifest their autism in personal as well as characteristic ways – and they may be responding to their own unique history in the context of their developmental disability. In a “comprehensive” evaluation of a complex patient, their unique presentation needs to be understood in order to intervene effectively. Projective assessment can help with this.

Historical Background

Projective testing was developed over the last century for use with adults and subsequently adapted for children. Over time, it has become apparent that the testing technique can help in the understanding of children with atypical as well as typical development, including individuals with autism.

Projective Technique

Any projective test is based on the projective hypothesis: given an ambiguous stimulus with no specific correct answer, the subject’s response will reflect their personal interests and concerns. The most commonly used projective instruments were actually designed for adults, with versions more appropriate for children and adolescents being developed later. Formal projective tests date to the early 1900s, when Herman Rorschach, a Swiss psychiatrist, developed the Rorschach technique. Henry Murray, a Harvard psychologist, developed the TAT in the 1930s and 1940s (Murray 1943). The initial CAT was developed in the late 1940s, using animals rather than people as characters in human situations based on the theory that children would readily (better) identify with them. In 1965, the human version (CAT-H) was produced. In keeping with the time in which it was developed, the Children’s Apperception Test scenes pulled for specific issues psychoanalytically conceived. Currently, the pictures are seen according to more general interpersonal and developmental frameworks. The RATC has followed from the early 1980s, providing a more modern appearance and effective scoring. The

Roberts-2 published in 2005 involved the updating of pictures and norms. The test approaches focusing on figure drawing were developed over the last century. Early on, Goodenough (1926) designed a system for scoring a male figure for intellectual maturity on the DAM. Over time, and especially since the 1940s, figure drawings have been of more interest as a projective technique (Koppitz 1968) than as a cognitive test (Harris 1963). Elaborations have included the DAP (where the individual is free to draw either sex or any age), DAF (where the drawing need not be the client's family), and HTP (where the objects requested are drawn on three pages, or as a variation, one page). The drawings might be supplemented by questions posed to the client. Over time, many versions of the SCT have been developed for different purposes, not only based on age and gender but also clinical population. In general, interpretation of projectives is based on the totality of the situation, including the patient's demeanor as well as what they saw, drew, or said. While early on projective interpretations may have been filtered through psychoanalytic understandings, currently interpretation typically involves more general, dynamic, and cognitive approaches. It should be noted that in a reciprocal development around thinking (and particularly relevant to autism), some psychological tests/tasks address social cognition or perception (e.g., subtests on theory of mind and affect recognition on the NEPSY-II) (Jura and Humphrey 2017).

Research Data

Over the years, and even early on, there has been considerable debate about the value of projective techniques in psychological research and clinical practice (Blatt 1975), with particular focus on the Rorschach and its scoring (Wood et al. 2001). It is not possible to review or evaluate the extensive literature here, beyond noting that projectives are the subject of controversy. However, as an example of this debate, a range of projective techniques and their scoring (Rorschach and TAT, as well as figure drawings such as the DAP) have been attacked (Lilienfeld et al. 2000) and defended (Hibbard 2003). The debate about projectives

has raged over the years, with a focus on the valid and ethical use of personality testing in general and the Rorschach in particular (Board of Trustees of the Society for Personality Assessment 2005). However, psychologists have continued to use projective tests in clinical practice and have continued to explore their usefulness in research. Some of this research has been done around autism, and much of the research around autism has involved the Rorschach. This is probably because more than other projective tests, the Rorschach can be scored, allowing measurements to be compared across groups. Some of the research has involved the similarities and differences: (1) between autistic individuals and controls with similar intellectual levels (Ishisaka et al. 1997), (2) between students with Asperger's Disorder and other emotional or behavioral problems (Holaday et al. 2001), (3) between individuals with Asperger's Disorder and "high-functioning autism" (Ghaziuddin et al. 1995; Nihei and Nihei 2008), as well as (4) between adults and older adolescents with "high-functioning autism" and a reference group with schizophrenia (Dyken et al. 1991). Because this list is not exhaustive and these studies tend to involve small numbers and focused issues, no attempt is made to review the findings here. However, taking the data in their entirety, they suggest individuals with ASD compared to controls have difficulties with cognitive integration as well as coping deficits, less interpersonal responsiveness, and more thinking problems. It is worth mentioning that in one study (Dyken et al. 1991), the schizophrenia index score was elevated among individuals with "high-functioning autism," although there was no reason (based on history or symptoms) to believe this was their diagnosis. In this study, lower PIQ scores were related to greater perceptual distortions. These data argue for the necessity of taking all information into account in assessing any case, but particularly around issues of autism. These studies also suggest that larger and more complete comparative studies around Rorschach scoring may provide useful information in understanding many diagnostic groups, including individuals with autism. However, regardless of the usefulness of the Rorschach (or other projective

tasks) in distinguishing autism from other conditions (normative or diagnostic), projective techniques can still be useful in (a) helping to understand complications of individual cases of autism, and (b) this understanding can involve identifying comorbid conditions, such as depressed or disorganized psychological states. For example, the Rorschach may be useful in assessing disorganized thinking in “higher-functioning autistic individuals” (Klin et al. 2005). The use of the Rorschach is described in specific cases of potential autism: including that of a complex youngster in a community setting to help clarify diagnostic issues (Fogler et al. 2019) and that of young adult to better understand possible symptom overlap (Frigaux et al. 2018). It should be noted that despite continuing controversy around the use of projectives in general and the Rorschach in particular, interest remains in the use of this instrument not just for descriptive but for diagnostic purposes in individuals along the autism spectrum (Crucitti et al. 2015; Kishimoto et al. 2016). Kleiger (2017) reviews some data, research, and concepts potentially relevant to Rorschach responding in individuals along the spectrum. However, the complications introduced by the diagnostic complexity of this spectrum disorder, along with small sample sizes focused on particular diagnostic issues, make assessing the utility of projective tests in autism difficult. As a result, projectives are apt to be most useful for descriptive rather than diagnostic purposes in autism for the foreseeable future.

Psychometric Data

Most projective tests are not literally scored. While some tests may claim to “measure” aspects of personality, often this involves systematic notations and analysis, and perhaps some coding (e.g., the CAT), rather than actual scoring. The notable exceptions are the Rorschach (Exner 2001) and the Roberts (Roberts and Gruber 2005). However, because the instruments involve many scales and scores, the issues of reliability and validity are particularly complex. As a result, psychologists should exercise some care in using these

instruments, particularly with unusual populations, such as individuals with autism. Just to add to the complications, readers should be aware that new instruments are constantly being introduced and old instruments (including scoring) updated.

Rorschach Method

Psychologists are probably most familiar with Exner’s Rorschach Comprehensive System (RCS), formulated in 1974. According to this system, each response to every blot is scored according to response location, quality, determinants, contents, organization, and special scores. All scores across the ten blots are tallied and compared to normative samples. Ultimately, any interpretation might reflect the patient’s capacity to think in an organized way, their psychological approach around personal concerns and the human sphere, in addition to their basic reality testing. Based on the response scores, a structural summary is compiled which reflects different aspects of the overall performance. These data are used to formulate many interpretive postulates concerning psychological characteristics and functioning. Once the measurements are obtained (which can appear as frequencies, ratios, or percentiles and can include derived scores and special indices), they are compared to tables of descriptive statistics organized by different factors, most importantly age. It is a complex system. Fortunately, the results can be analyzed by computer. Because of the complexity of the scoring and analysis, some clinicians (perhaps especially those seeing particular child populations) may at times forgo formal scoring. They do this with full knowledge of Rorschach notation and interpretation, as well as relevant clinical experience. They use the Rorschach as part of a battery of tests, not so much to support a diagnosis as to enrich their psychological understanding of the individual client. Readers should be aware that since Exner’s death in 2006, there have been ongoing efforts to sustain his scoring system, and there is a computer scoring program for it (Rorschach Interpretation Assistance Program: Version 5 [RIAP5]). However, some professionals have begun to develop an alternative system. Readers should know that

Exner's RCS (Rorschach Comprehensive System) has been revised and reformulated in an essentially overlapping and coexisting but separate scoring system designated R-PAS (Rorschach Performance Assessment System, manual published 2011). R-PAS has been developed by a group which includes professionals who worked on Exner's earlier research council, and who believe R-PAS significantly extends the work undertaken by that previous group. Both systems are evidence-based, with the main validating evidence for the Rorschach coming from research based on the RCS (Mihura et al. 2013). Both systems have access to international norms (Composite International Reference Values, or CIRVs) based on the RCS (Meyer et al. 2007). However, it should be noted the adult samples from around the world are more stable than the child and adolescent samples. An online feature of R-PAS may allow for updating norms and data as new information becomes available. While there are currently no data speaking to the utility of R-PAS in the assessment of autism, it might be expected to perform similarly to the Exner RCS and require a good deal of clinical experience and judgement to be helpful.

Roberts Test

On the Roberts (RATC, Roberts-2), each story is scored separately on a number of rating categories. Check marks are made indicating that certain psychological factors (on developmental/adaptive and clinical scales) have been present in the stories. These data are summed and analyzed. Profiles (according to age group) are plotted based on these scores, reflecting, for example, reliance on others, basic human emotions, or even atypical responding. Together, the data are thought to reflect the child's feelings and reactions in the interpersonal sphere. The Roberts describes ways for both quantitative analysis (using T-scores) and qualitative interpretation (using clinical judgment). The manual provides descriptive statistics, as well as comments on reliability and validity studies. Because of the scoring, repeat testing can be particularly informative in assessing progress over time. It is acknowledged that only very general clinical inferences can be

made and that clinicians must use skill and judgment in interpreting results.

Other Instruments

It is worth noting that other projective instruments might be subject to scoring or systematic analysis. For example, the DAM can be scored for intellectual maturity. And Rotter et al. (1992) have published scorable version of the SCT. Various scoring systems for the TAT have been developed. However, for the most part, the thematic tests have not been made amenable to strategic scoring or normative data of the sort which would allow for specific data analysis or diagnostic comparisons. All the same, professionals remain interested in more systematic approaches to projective testing, including the scoring of thematic stories (Jenkins 2008).

Other Issues

Professionals have been concerned not only about the subjective aspect of the analysis of projective data but also the lack of racial sensitivity reflected in the thematic stimuli. Some of the more recently developed instruments have provided procedures and pictures which recognize ethnic/racial/cultural diversity (including the Roberts-2). Professionals tend to assume that the disruptions in relating and communication in the case of autism are so basic that they transcend racial/ethnic considerations. All the same, it would always be prudent to consider whether cultural tensions have exacerbated or distorted social issues as they present in testing and in life.

General Comment

It is often lamented that normative (objective) data are not provided for all projective instruments. However, even when such normative data are available, one still needs to ponder their use. Norms are usually provided on large national samples of typical children and adults. While such general normative data might facilitate the comparison of a client to population norms, when their data deviate from that of "typical" individuals, one still needs to account for differences. Differences might be associated with autism, or any number of other possibilities, all of which need to be considered. Further, data describing diagnostic groups or their psychological features

are not easily accessible, including data for autism. Generally speaking, even when features of a diagnostic group might be identified (and even through scoring), the final diagnostic determination is not necessarily clear. It is still up to the clinician to make a decision whether a client meets criteria for a specific diagnosis or not, based on the entirety of the available data. The diagnostic process involving projectives remains largely descriptive and supportive – perhaps particularly in the case of children and adolescents, and especially in the case of autism.

Clinical Uses

In the context of a comprehensive assessment of autism, projectives are potentially a useful addition. However, much needs to be considered.

Diagnostic Clarity: It is worth reiterating that projective testing may supplement and enrich the understanding of clients, including those along the autistic spectrum, but it may not always be directly relevant to the making of an actual diagnosis. All the same, the profile suggested by projective testing can be seen as consistent with a diagnosis of autism or perhaps can suggest some other (alternative or comorbid) condition which needs further evaluation. These comorbid conditions can include psychosis, depression, or anxiety, all of which may require medical as well as behavioral interventions (e.g., cognitive behavioral therapy). Testing may help to identify the need for attention to particular issues within more common treatments, such as parent training or social skills group. For example, projectives can help make very real the fact the child often does not know what is going on – and how confused, distressed, and disruptive they can become as a result. In this context, caretakers may need to focus on a child's social misperceptions and/or social anxiety (along with general skills deficits) before they can expect compliant or adaptive behavior.

Complicated Situation: According to DSM, diagnoses are clinical entities and, for the most part,

are made based on criteria related to history and presentation. Autism screening and diagnostic tools have evolved over time. In this context, it needs to be acknowledged that autism rating scales may or may not detect autism, and even observations and interviews have limitations. Parent report is dependent on parent impression, and behavioral observation relies on current behavior. Ultimately, the diagnosis must be made based on a constellation of information. Projective testing provides a way of assessing the unique features of any client, regardless of diagnosis; projectives will always be relevant to the kinds of unusual cognition, social disruption, and emotional approach which are characteristic of autism.

Case Selection: While it is tempting to say that projective assessment is most likely to be relevant in the cases of “high-functioning” individuals who have the capacity to deal with the directions and responding involved in projective testing, in fact projectives are given to individuals of many ages, including young children, chronologically and/or developmentally (Jura and Sigman 1985). In determining whether a patient along the spectrum might benefit from projective testing, professionals and parents should think in terms of developmental and skill level/s, and whether the child can understand and respond to the actual tasks being proposed. Where an individual (autistic or otherwise) might be dealing with intellectual challenges, the concept of mental age also comes into the interpretative process. The psychologist needs to ask to what extent the client's mental age accounts for his or her projective performance long before they consider other diagnostic possibilities.

Beyond Diagnosis: More recently, in the assessment of diagnosis, the emphasis has been on evidence-based instruments and identifiable treatment outcomes (Ozonoff et al. 2005). At the same time, the basic theory behind best practices has been to provide as comprehensive and relevant an evaluation as practically possible in order to individualize and maximize treatment. While Klin et al. (2005) have noted that projective testing may typically be

more optional than other assessments in autism, they identify projective approaches as useful with some patients. Particularly based on the battery of projectives described here, the psychologist can comment on an individual's cognitive comprehension, interpersonal style, and personal issues as they impact adjustment. For example, projective testing can help to focus caretakers on issues of pressure, and the need to increase structure and reduce stress. In general, projective testing can provide an opportunity for the adults to begin to comprehend a youngster in his or her own terms and to become sympathetic with their child's dilemma given how they understand the world in which they live. Projectives can help caretakers as well as patients themselves to make better sense of their experience. Sometimes, simply knowing what has been going on in a more specific cognitive, social, and/or emotional way allows caretakers and patients to respond differently and more effectively. Sometimes, very specific features of the testing can prompt further evaluation or specific intervention. At times in extreme cases, particularly where medication is involved, projective testing can be repeated after an appropriate interval of time in order to document whether progress is being made.

It needs to be acknowledged that autism is a complex and heterogeneous condition involving social and communication impairments and deficits, as well as restricted, repetitive patterns of interests, behaviors, or activities. Much needs to be done beyond diagnosing autism in some general way. A full workup often involves a number of assessments (including intellectual and academic achievement tests) in addition to specific evaluations (e.g., with a speech/language pathologist or occupational therapist or neuropsychologist). Certain medical consultations and procedures may also be in order. Any psychological testing, projective or otherwise, is deeply embedded in an elaborate evaluation process in order to assess the needs of any individual with autism and to make appropriate behavioral and medical recommendations.

Prompt Dependence

Brian Reichow

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Anita Zucker Center for Excellence in Early Childhood Studies, University of Florida, Gainesville, FL, USA

Definition

Prompt dependence refers to a situation in which a child or adult does not perform a behavior until they are prompted. Prompt dependency is a common problem for individuals with autism spectrum

disorders (ASDs). Individuals with ASDs frequently only perform skills and behaviors they have acquired when asked to do so by an adult, regardless of whether or not natural prompts are present. For example, you might have a child that knows all of the steps of how to brush their teeth independently, but needs an adult to prompt them before beginning each step. Because prompt dependency is undesirable (we want to teach individuals to perform behaviors independently), it is essential to systematically fade prompts and thin reinforcement schedules to ensure that stimulus control is transferred to naturally occurring stimuli and reinforcers.

from a physical prompt, a gesture, a verbal prompt, or no prompt at all where the individual is able to complete a task independently. A physical prompt can be lightly guiding the child into an activity or a more intense prompt where the child is completely guided in a hand over hand. A verbal prompt also has a range of cues, such as telling the child what to do or say, or just reminding the child, but not directly telling them what is expected. Prompts should be systematically decreased until the child is able to independently complete activities, so that the child does not become prompt dependent (McDonnell and Ferguson 1989).

PROMPT System

Megan Lyons
Laboratory of Developmental Communication Disorders, Yale Social and Affective Neurodevelopment of Autism Program, Yale Child Study Center, New Haven, CT, USA

Definition

Prompts for Restructuring Oral Muscular Phonetic Targets (PROMPT; Hayden-Chumpelik, 1984) is a speech therapy technique that utilizes tactile, visual, and positioning cues through manipulation of the tongue, lips, and jaw as well as other structures responsible for speech. The PROMPT

technique is done by PROMPT-certified speech-language pathologists who physically guide the speech structures to elicit typical movement patterns for more intelligible speech. For children with ASD who are sometimes thought to have difficulty with motor-speech production (e.g., apraxia), the use of PROMPTs is hypothesized to improve control over the speech structures, thereby enhancing functional communication skills.

Historical Background

PROMPT was first developed in the late 1970s for children who exhibited difficulties with motor-speech production and who were not responding to traditional therapies. The PROMPT technique stemmed from work done in the fields of neurobiology, cognitive-linguistics, and social aspects which form the basis of this approach. The focus of PROMPT treatment has recently shifted from emphasis on motor placement and planning to broader social-communicative and language goals. However, no empirical support for these broader goals has as yet been provided.

Rationale or Underlying Theory

PROMPT's use of tactile, visual, and positioning cues stemmed from work examining the tactile system (e.g., visual, auditory) in both normal and abnormal brains. It is based on the hypothesis that apraxic difficulties can be addressed by concentrated practice in articulatory postures and movements.

Goals and Objectives

The goal of PROMPT therapy is to improve speech intelligibility and to enhance overall functional communication skills.

Treatment Participants

Originators claim that PROMPTs can be used with infants as young as 6 months old through adulthood. Empirical evidence for this claim is lacking.

Treatment Procedures

PROMPTs are tactile, visual, and positioning cues done by a PROMPTs-certified clinician who guides a participant's speech structures through the movements necessary to produce intelligible speech. The focus is on both the sequence and transitions of movements for speech production through practice.

Efficacy Information

Little empirical evidence to currently support this therapeutic approach.

Outcome Measurement

Increased speech-sound production and intelligibility for functional communication.

Qualifications of Treatment Providers

PROMPT-trained speech-language pathologists use this therapeutic technique. In addition, there is a parent training program taught by the child's clinician with the focus on helping parents with strategies for working with their own child.

Synonyms

Prompts

Definition

A prompt is something an adult does to help someone perform a behavior (MacDuff et al. 2001; Wolery et al. 1992). The purpose of a prompt is “to cause students to perform the target behavior so that it can be reinforced when the target stimulus is present” (Wolery et al. 1992, pp. 42–43). Prompts give someone clues about how to perform a behavior and varying levels of assistance on how to perform it (e.g., verbally telling a child to say wave good-bye, providing a motor model of waving good-bye, placing your hand behind a child’s hand and assisting them in performing the actions of waving good-bye). Prompts are not cues or task directions; cues or task directions inform the child that it is time to perform a behavior, whereas a prompt provides assistance to the child that helps them do the behavior (Wolery et al. 1992). There

are many different types of prompts that can be classified in multiple ways (Reichow and Reichow 2012; Wolery et al. 1992). One way we can describe and classify prompts is with respect to the method of presenting the prompt and how it looks. A second way to classify prompts is along a continuum of how much assistance they provide to an individual (e.g., a gestural prompt provides less assistance than a hand-over-hand prompt). A third way that we can classify prompts is with respect to the behavior of the individual being prompted – i.e., whether or not they perform the correct behavior after the prompt. Additional information on prompts and prompting can be found in the Autism Internet Module website (<http://www.autisminternetmodules.org/>) on prompting (Neitzel and Wolery 2010).

Pronoun Errors

Jennifer Arnold

Department of Psychology, University of North Carolina, Chapel Hill, NC, USA

Definition

Pronouns are noun phrases that depend on the context for interpretation. For example, first (*I, we*) and second (*you*) person pronouns are defined by the speaker and the addressee, which shifts from one situation to the next. Third person pronouns (e.g., *he, she, they, it*) are also dependent on the context and are typically used to refer to things that are salient in the discourse or environment. Because pronouns interact with many aspects of language knowledge, there are several types of potential errors.

Although grammatical errors are possible (e.g., saying *me* for *I*, or *he* for *she*), most of the literature on the language of Autism Spectrum Disorder (ASD) has focused on pragmatic pronoun errors of several types. One commonly reported error is the use of third person referential expressions (like the speaker's own name, or a pronoun *he* or *she*) instead of the pronouns *I* or *you*. Research has also shown that speakers with ASD sometimes use over-specific expressions, like a name or description when a pronoun would be understandable in context. Another type of error is the use of a pronoun when the referent is not clear in the context. Such ambiguous pronouns are not frequently attested, but have sometimes been found to occur in the speech of individuals with ASD.

An often-cited type of error is pronoun reversal, which occurs when the words *I* and *you* (or *we* and *you*) are switched. For example, Lee, Hobson, and Chiat (1994) report a child saying to his teacher "I'm better now" when the teacher had been sick. This type of error was reported by Kanner (1943) in his seminal case study and since then has been frequently cited as a language characteristic associated with autism. However, contrary to this widespread attention, pronoun reversals are neither a defining characteristic of autism nor even a frequent one (e.g., Jordan 1989; Lee et al. 1994).

Pronoun Use

Jennifer Arnold
Department of Psychology, University of North Carolina, Chapel Hill, NC, USA

Definition

Pronouns (e.g., *I, you, she, he, it, they, us, me, him, her, them, this, that*) are noun phrases that typically refer to people or things that are easily understood in context. Pronouns contain very little explicit lexical information. For example, personal pronouns in English encode gender (e.g., *she* vs. *he*), number (e.g., singular *I* vs. plural *we*), and person (e.g., first person *I* vs. second person *you* vs. third person *she*). Some languages (like Spanish) use null reference forms that are absent completely (e.g., *canto* = *I sing*).

Pronouns therefore depend on the physical context, discourse context, or background information for interpretation. First and second person pronouns (*I, we, you*) change their referents depending on who is speaking. Third person pronouns (e.g., *he, they, it*) also depend on the context for appropriate usage and interpretation, and are generally considered to refer to the most salient or accessible entity in the context that matches the grammatical properties of the pronoun. This situational dependence requires pragmatic knowledge, making pronoun use an area of potential difficulty for those with Autism Spectrum Disorder (ASD).

Historical Background

In Kanner's (1943) initial description of the characteristics of autism, he noted that some children with autism used pronouns inappropriately, for example, using *you* instead of *I*. For example, his first case study, Donald, was reported to say "you did not fall down" at age 5, to describe a situation where he himself nearly fell. Since then, similar errors have been widely attested. However, despite the salience of these errors, systematic studies of pronoun use and understanding have found that pronoun reversals are neither ubiquitous nor as frequent as Kanner's focus on them would suggest (e.g., Jordan 1989; Lee et al. 1994).

Current Knowledge

Pronoun Use in Typical Speech

The ability to use pronouns correctly requires both (1) grammatical knowledge and (2) pragmatic knowledge about their function. Grammatical knowledge is required because pronouns in languages like English mark properties of the referent (e.g., person, number, gender), as well as its syntactic (i.e., structural) role, for example, using *we* in subject position and *us* in object position. Speakers use this grammatical knowledge to select the correct pronoun when speaking, for example, *he* versus *she*, and to successfully interpret pronouns during language comprehension.

Pronouns are also unusual in the degree to which their interpretation is relative to the speaker and context. This requires language users to understand the pragmatic function of pronouns in order to successfully establish reference. That is, the intended referent of a pronoun changes from one situation to the next. It is this aspect of pronouns that has received the most attention in the literature about language and ASD.

The relativity of pronouns is especially salient for *I/we* and *you*, which have different referents depending on who is speaking. But the context is also important for the appropriate use of third person pronouns, like *he*, *they*, or *it*. First, the context determines whether a pronoun is appropriate at all, as opposed to some other form of reference. For example, I could say *he*, *my cat*, *Julio*, *the brown and white cat*, or *that furry creature* to refer to the same entity. Speakers must use their pragmatic knowledge about appropriate language use to choose the best expression for a particular linguistic and social context. A too explicit expression sounds awkward and redundant (e.g., *Julio ate kibble for breakfast. Julio went outside. Julio took a nap*), whereas a too general expression is ambiguous (e.g., *My cat and my son were playing. He fell down.*) Listeners also must rely on pragmatic knowledge to interpret pronouns. All forms of reference are ambiguous at some level (e.g., there are many Julios in the world), but pronouns are especially ambiguous. One view is that appropriate production and comprehension of pronouns relies on representations of the knowledge and attention of one's interlocutor, which are related to theory of mind (e.g., Bard and Aylett 2004; Bard et al. 2000; Gundel et al. 1993). It is also well established that pronoun use is highly constrained by the discourse context, which does not necessarily require theory-of-mind representations. For example, pronouns tend to be used for reference to recently and prominently mentioned things (Arnold 2008).

Pronouns thus participate in a complex set of grammatical and pragmatic knowledge about language use. Some of this knowledge is absolute, like the fact that *I* is used for the speaker and *you* is used for the addressee. Thus, errors of pronoun

reversal can be unambiguously identified if the speaker's intended meaning is known. But much of this knowledge is gradient. For example, in the passage above about Julio, the repeated mention of his name is awkward, but not ungrammatical. As an example of a too general expression, consider a quote from Kanner (1943): "The father made a special point of mentioning that Donald even failed to pay the slightest attention to Santa Claus in full regalia" (p. 218). If *Donald* were replaced by *he*, the referent would be somewhat ambiguous, but still understandable in context. Thus, assessments of an individual's ability to use pronouns need to take into consider the range of possible alternatives.

Pronoun Use in Autism Spectrum Disorder

Individuals with ASD often use language differently than their peers. These differences can relate to pronouns and the broader system of reference in several ways. Three potential areas of difference are discussed here: (a) Pronoun reversal, (b) treating first person references as third person, and (c) the pragmatically appropriate use of pronouns within the referential system more broadly, with a focus on third person reference (e.g., *he*, *she*, *it*, *they*).

Pronoun reversal. Much attention has been given to reports that individuals with ASD sometimes make errors referring to themselves. One such error is pronoun reversal, using *I* to refer to one's addressee, and *you* to refer to oneself. Lee et al. (1994) described an incident where a boy's teacher had just returned from sick leave, and he said to her "I'm better now," and another case where a 19-year-old subject said "Thank you for seeing you, Tony" at the end of the experimental session. These utterances are notable because they are readily identified as errors. Pronoun reversal errors also attested for typically developing toddlers, but are relatively rare, and tend to disappear by around 3 years of age (Clark 1978). However, one should not conclude that these errors occur in all instances, nor even that they occur for all children with ASD.

For example, Jordan (1989) found that the children with ASD in her study had some difficulty producing, but not understanding, pronouns.

However, the most common errors were a name instead of you or I, or using the wrong case pronoun, and not the reversal of you and I. Even the three subjects (out of ten with ASD) in her study who did produce at least one reversal did not do so all the time. Similarly, Lee et al. (1994) found a few cases of pronoun reversal in their ASD group, but not their developmental delay group. However, this was not the most frequent type of pronoun error, and there were almost no errors in comprehension of personal pronouns.

Nevertheless, pronoun reversals are attested more often for individuals with ASD than other groups. Several explanations have been proposed. One view is that reversals reflect a difficulty representing one's social identity, or distinguishing oneself from others (Charney 1980; Lee et al. 1994). Another possibility is that it results from the use of echolalia, that is, the tendency to repeat others' utterances, especially the ends of utterances where "you" is more commonly found than "I" (Bartak and Rutter 1974). Other authors have suggested that the correct use of personal pronouns is related to joint attention (Loveland and Landry 1986), or attention to the linguistic exchanges of others (Oshima-Takane and Benaroya 1989).

Treating you and I as a third person. Another pronoun error often associated with ASD is the use of proper names or third person pronouns instead of *I* or *you*. This type of error emerged in Lee et al.'s (1994) study, which used questions to elicit answers that would most naturally use *you* or *I*. A frequent type of error was the use of the experimenter's name or the participant's own name instead of a pronoun. However, it is worth noting that these were equally frequent in both the ASD and the comparison group of children with mild intellectual disability. Jordan (1989) also found that children with ASD frequently used their own name or the experimenter's name instead of *you* or *I*, and in this regard differed significantly from both the group with intellectual disability and the typically developing group.

The use of a proper name or third person pronoun is not semantically incorrect, in that it does communicate the intended referent. However, it does not follow the pragmatic rules of language use, that is, the appropriate use of language in context. Thus, using a third person reference

fails to adopt the convention of marking the speaker and addressee as the participants in the conversation, which is an important part of marking one's perspective in discourse.

Pragmatically appropriate third person reference. Pronouns are an important part of language because they allow us to refer to people and things, but they do not merely carry information about referential identity. The use of a pronoun also communicates something about the speaker's perspective on the referent or the situation. Pronouns tend to be reserved for things that are highly salient in the situation, whereas names and descriptions tend to be used for reference to less prominent entities.

This means that learning how to use pronouns appropriately includes learning that they are meant to indicate salient referents, and learning how to select the best reference form for the current situation. This choice applies mostly to third person references (e.g., *Mia* vs. *she*). By contrast, the discourse participants (*I*, *you*, *we*) are naturally salient in the context, and thus always should be referred to with pronouns.

Analysis of typical language use has identified numerous discourse properties that pattern with the use of pronouns. Speakers and writers typically introduce a character or object with a full name or noun phrase. Subsequent references can be pronominal, depending on a variety of factors stemming from the discourse context and the speaker's judgment about how interpretable the pronoun is. For example, pronouns are used more often for things mentioned recently, and especially in prominent syntactic positions, like grammatical subject (see Arnold 2008).

The question is whether individuals with ASD produce third person reference differently than other groups of speakers. Differences could emerge as a tendency to produce over-ambiguous speech, for example, using a pronoun in a context where the referent is not clear. Alternatively, differences could reflect a tendency to use overspecific forms, avoiding pronouns when they would be appropriate. Evidence has demonstrated that highly verbal individuals with ASD are generally sensitive to discourse constraints, and observed differences are a matter of degree, not complete failure to understand the referential system. Where

differences emerge, they are primarily in the direction of overspecification, but some studies have also reported increased ambiguity.

For example, Arnold, Bennetto, and Diehl (2009) analyzed spoken narratives produced by children and adolescents with ASD, and a well-matched group of their typically developing peers. They found that pronoun use was driven by the discourse context for both the younger (age 9–12) and older (age 13–17) groups, both with and without ASD. That is, pronouns were used most often when the referent had been last mentioned as the grammatical subject of the preceding utterance, and new introductions were almost always with a full name or description. But at the same time, the younger children with ASD displayed a slight bias toward overspecific forms. This is consistent with the observation of Baltaxe (1977) that many adults with ASD used referential expressions that were more specific than needed, and with evidence of using names instead of first and second person pronouns (see above). This tendency emerged only in those cases where the discourse context was less constraining, which highlights the importance of assessing referential behavior within the context of a fine-grained discourse analysis. As another example, Colle, Baron-Cohen, Wheelwright, and van der Lely (2008) examined referential choices made by adults in a story-telling task. The adults in both the ASD and control groups were similar in their use of explicit expressions to introduce or reintroduce characters, and for the most part used pronouns to maintain reference. At the same time, the autism group was relatively less likely to use pronouns for maintenance than the control group, again showing a bias toward overspecific reference.

Some studies have also reported that speakers with ASD may use ambiguous reference more than comparison groups. For example, the participants in Colle et al.'s (2008) study were more likely to use ambiguous pronouns for reference to one of the characters. Similarly, Tager-Flusberg (1995) asked children to tell a story from a picture book. Children in the ASD group were more likely to introduce a new character for the first time with a pronoun.

Our understanding of how reference production is related to ASD also comes from studies on

related aspects of reference, such as producing additional description when necessary. When the referent is salient or identifiable, a simple expression is sufficient (e.g., *the cup*), whereas additional description is necessary when a second possible referent is in the context (e.g., *the short cup*). Nadig, Vivanti, and Ozonoff (2009) found that the children with autism in their sample displayed individual differences. Some, who had higher structural language levels, behaved just like the typically developing group, adapting their expressions to both their own and their partner's perspectives. However, some failed to adapt their expressions at all, and some only adapted to their own perspective.

In sum, sometimes ASD is associated with errors in pronoun use, in particular the overuse of names or labels instead of the pronouns *you* and *I*, and on occasion the reversal of first and second pronouns. At the same time, many individuals with ASD have demonstrated sophisticated abilities to use pronouns appropriately within the discourse context.

Future Directions

Research has established that the pragmatic use of pronouns and other referential expressions is sometimes affected by ASD. Yet it appears that pronoun use strategies are not the same for all individuals with ASD. Future research is needed to better understand individual differences in referential strategies, and the range of both successes and difficulties with reference associated with ASD. To this end, detailed linguistic analyses are needed in order to precisely identify the contexts in which speakers with ASD may use pronouns and other forms of reference differently than other groups.

Further research is also needed to better understand whether ASD impacts the comprehension of pronouns. Question-answering studies have found good pronoun comprehension among individuals with and without ASD, but these say little about moment-by-moment processing. Further work is needed to assess whether individuals with ASD are sensitive to the appropriateness of particular types of

referential forms in a given context, and how referential processing proceeds in real time.

Prosocial Behavior

Geralyn Timler
Speech Pathology and Audiology, Miami
University, Oxford, OH, USA

Definition

Prosocial behaviors include a range of positive and friendly behaviors that individuals display toward others. In children, these behaviors include sharing, helping, and taking turns with others, cooperating with others to achieve a common goal, and negotiating with others to reach a mutually acceptable

compromise when a conflict occurs (Bierman 2004; Grusec et al. 2002; Ladd 2005). Prosocial behaviors are important to children's success in peer interactions. Children whose words and actions are perceived as prosocial are viewed more favorably by their peers than those whose words and actions are viewed as indifferent, passive, hostile, or irrelevant (Coie et al. 1990). Most social communication interventions aim to increase prosocial behaviors and may include specific activities to teach children to produce polite requests, compliment each other, respond to other's comments and questions, and resolve conflicts by staying calm and suggesting a compromise.

Definition

Prosody refers to the rhythm and melody of the voice, including intonation, stress, and pauses. Prosody can provide cues to lexical meaning, (e.g., CONtract vs. conTRACT), grammatical structure, emphasis (e.g., I want THIS cookie), affect, and structure in discourse (e.g., asking a question or making a statement), among other functions.

P

Historical Background

In their initial descriptions of the disorder, both Leo Kanner and Hans Asperger noted the presence of differences in tone of voice used by children with autism spectrum disorder (ASD). Asperger noted that the children with this disorder could sound too soft and far away, shrill, and have intonation with a singsong quality or that did not go down appropriately at the end of a declarative statement. Descriptions of prosody have ranged from flat or monotonous to variable, pedantic, and/or having a singsong quality. Because of this variability in symptom presentation across the autism spectrum, it has been historically difficult to identify which characteristics of prosody production are “autistic-like.” As a result, it has been difficult to conduct

research on the topic, and more notably, few researchers have attempted to develop interventions to directly address prosodic differences.

Early attempts to characterize prosodic performance in individuals with ASD divided prosody skills into broad categories such as “linguistic” prosody (i.e., types of prosody that communicate sentence structure, discourse structure, word meaning, among others) and “affective” prosody, based on the theory that children with ASD would have difficulty with judging emotions in tone of voice. More recently, researchers have focused on the nuanced nature of prosody comprehension and production, and its integration with words, grammatical rules, gestures, and facial expression. Notably, researchers have focused on profiles of performance across pragmatic communication skills and its potential as an early diagnostic marker for ASD.

It should be noted that knowledge about prosody has historically lagged behind other areas of language research (such as syntax or semantics) in both typical and disordered populations. This lag in research has primarily been because of its complexity as a construct, difficulties in assessment, and its variable presentation in communication. Whereas syntax follows a set of rules that are consistently observable by most native speakers of a language, prosodic cues can be interpreted differently by different people, especially when the prosody is in conflict with other semantic or contextual information (e.g., irony or sarcasm). Similarly, research on prosodic performance in individuals with ASDs has been hindered by the relatively small (amongst communication domains) amount of research on normative samples.

Current Knowledge

Prosody refers to the patterns of rhythm, intonation, and stress of the voice. Prosody is considered to be a *suprasegmental* element of speech, meaning that one prosodic pattern can include more than just one sound or word, but potentially an entire sentence or conversation. Prosody has many functions in language and can be used to

clarify linguistic, pragmatic, and affective aspects of an utterance.

At the word level, prosody marks lexical and syntactic distinctions. *Lexical stress* can affect the meaning of the word, depending on which syllable is emphasized. For example, the word “CONtract” refers to a legally binding document, whereas “conTRACT” is a verb meaning “to shrink.” Individually stressed words within a sentence can also function emphatically (e.g., “It was a REALLY big fish!”), or contrastively, to draw attention to a difference from a word in a previous clause or sentence (e.g., “I have a blue car and she has a GREEN one.”) or repair a miscommunication (e.g., “Did you order chocolate cake?” “No, I ordered chocolate ICE CREAM.”). These uses are sometimes called “linguistic” or “grammatical” prosody to differentiate them from prosodic patterns that express affect (or “affective” prosody).

At the sentence level, prosody can have both grammatical and affective/pragmatic functions. Grammatically, prosodic cues can be used to identify clausal boundaries, clarifying sentences that might otherwise be ambiguous. For example, by altering the rhythmic pattern of pauses in a sentence, we can change “The man (pause) tapped the woman (pause) with the cane.” (i.e., the man used a cane to tap a woman) to “The man tapped (pause) the woman with the cane.” (i.e., the man tapped a woman who uses a cane).

Sentence-level prosody can also convey social and affective information. Intonation patterns often indicate the pragmatic function of a sentence: whether it is a statement or a question, and whether it is intended literally or sarcastically. Further, prosodic cues can communicate the speaker’s affective state, providing additional subtext to an utterance. For example, “My sister will be in town next week” could be said with excitement or with dismay, with each version shedding light on the relationship between the speaker and his sibling, and suggesting what the appropriate response might be. Listeners can also use prosody to identify a speaker’s accent, which can provide information about regional origins and social status.

Prosodic Development

While most adults can use prosody for all of these purposes, our knowledge of the developmental trajectory of these skills is in its infancy. Research on prosody is particularly difficult to conduct due to the wide variety of acoustic cues that can be used to indicate stress, such as pitch (fundamental frequency) and intensity changes, vocalic lengthening, and pauses. Further, it is impossible to completely separate prosodic cues from the lexical content of an utterance, and thus prosody must be considered in context.

In typically developing children, prosody is one of the earliest (if not the earliest) social abilities to develop. Fetuses can hear and respond to vocal patterns in utero. Within the first few days after birth, children can differentiate between their mother's voice and other voices. Moreover, newborns are able to differentiate between the prosodic patterns of their native language and a foreign language.

Prosodic features of language are present very early in language production. Even at the babbling stage, children produce sentence-like strings of sounds that conform to the intonation patterns of their native language. As children incorporate words into their vocabulary and begin to combine them into sentences, these utterances tend to have not only the word order but also the prosodic patterns of adult speech. In some areas of language acquisition, as in the case of forming questions, the use of prosodic cues precedes that of syntactic cues, with children using a rising intonation to indicate a question ("You go store?") before they are able to invert the subject and object ("Is he happy?") or insert auxiliaries ("Do you like ice cream?").

In the domain of comprehension, typically developing children are able to glean affective information from prosodic cues from infancy. Even before they have the vocabulary to understand their mother's speech, they are able to decipher whether she is happy or angry from her tone of voice. Later, children are able to use lexical stress cues to differentiate between words that contrast on stress patterns alone. By school age, children can use intonation patterns to

interpret syntactically ambiguous sentences. Finally, around age 8, children begin to be able to understand the more complex pragmatic prosodic cues, such as sarcasm, a meaning in which prosody contrasts with lexical meaning and/or contextual meaning to provide an alternate mental state. Prior to this, most children will interpret all statements literally, regardless of tone of voice.

Prosody in Autism Spectrum Disorders

Prosodic impairments are common across individuals with ASDs, including individuals who have intact structural linguistic abilities. In production, individuals with autism are often noted for having unusual prosody in their speech, either for speaking in a flat, monotone, or robotic manner or for having an exaggerated or otherwise odd style of speaking. In studies examining stress patterns, participants with ASD have been shown to be more likely than controls to misassign stress or to accent multiple elements in a sentence, rather than highlighting only key words.

Individuals with ASD seem to have an uneven profile with respect to comprehension of prosody. Several studies have shown impairments in using prosodic cues to understand affect and mental states. Studies have been more mixed with respect to other linguistic or pragmatic uses of prosody, with findings generally suggesting more impairment in sentence-level processing, with more spared prosodic comprehension for word stress and question contours. Findings for differences in prosodic production have been surprisingly limited, despite the pervasive nature of clinical reports of prosodic differences, and there is a need for more studies of subtle acoustic differences in prosodic patterns produced by individuals with ASD.

Assessment and Treatment of Prosodic Disorders

Prosodic disorders are notoriously difficult to assess objectively and to treat. Clinically, prosodic impairments are often diagnosed based on the

therapist's subjective judgments of "oddness," and a determination of whether any atypical speech patterns can be accounted for by other articulatory or phonological disorders. A few standardized measures have been developed to test prosodic abilities in children, including the Prosody-Voice Screening Profile (PVSP) and the Profiling Elements of Prosodic Systems for Children (PEPS-C). Generally, prosodic disorders are identified in the domain of language production. To this end, the PVSP analyzes samples of a child's natural speech and compares them to a normative database to find atypical prosodic patterns. However, to score this test, one must be able to transcribe prosody, which requires a great deal of time and training, making it less practical for typical clinical settings. The PEPS-C is a more structured assessment, which makes it possible to elicit language that uses prosody in a variety of functions such as phrasing, focus, and affect. This test includes both a production and a comprehension component using audio CDs and thus can be used to test receptive as well as expressive prosodic abilities.

There is currently no standard treatment for prosodic disorders. Speech therapists might model appropriate speech patterns for their clients or use Melodic Intonation Therapy, which first presents pitch patterns and rhythms with humming, and progressively approximates natural speech. Other therapies have been developed that focus on specific areas of prosody such as stress placement as well. Future research should focus on developing and testing interventions for prosodic impairments as this is an area that has been somewhat neglected in treatment plans. For high-functioning children with autism, odd prosody can be an obstacle in gaining social acceptance with peers.

Future Directions

Future research should utilize acoustic characteristics of the speech signal to characterize some of the subtle differences in prosody production that children with ASD exhibit. Future studies should focus on developing assessment techniques and

interventions for prosodic impairment. Furthermore, automatic analysis of the acoustic signal is promising for evaluation and instant feedback during therapy. In all areas of research, assessment, and treatment, it will be very important to be sensitive to individual differences in prosodic abilities and deficits, as these differences might be informative (i.e., a "bellwether") for an individual's specific cognitive/linguistic strengths and weaknesses.

Prosody-Voice Screening Protocol

Sue Peppé

High Appin, Tynron, Thornhill, UK

Synonyms

PVSP

Definition

The Prosody-Voice Screening Profile (PVSP) is a test of prosody production. The PVSP collects spontaneous speech in order to assess the prosodic and vocal characteristics of the speaker. Phrasing, rate, stress, pitch loudness, and vocal quality are transcribed and judged for appropriateness. It is suitable for use with children and adults; assesses expressive but not receptive prosodic ability; and has normative data to which comparisons can be made.

Prospective Memory in Autism Spectrum Disorder

Amanda Roestorf¹ and Catherine Grainger²

¹Department of Psychology, Faculty of Natural Sciences, University of Stirling, Stirling, Scotland

²Psychology, University of Stirling, Stirling, Scotland, UK

Synonyms

Everyday memory; Memory for future actions; Memory for intentions; PM; ProM; Remembering to remember

Definition

“Prospective memory” (PM) is a form of memory that involves remembering in the future – i.e., “remembering to remember.” More specifically, PM engages many parallel cognitive functions to plan a future goal (task, thought, or action; “intention formation”), to be carried out (“intention initiation”) at a defined future point (“intention execution”), usually after a delayed period of time (“retention interval”). Successful PM not only depends on correctly recalling “when” to act, but also recalling appropriate information (“what” to remember) about the planned goal or action (“intention retrieval”) in the appropriate context (“how” to act on the intention). PM intentions are usually carried out during the course of unrelated ongoing activities and, therefore, draw on executive function resources, such as working memory, attention monitoring, planning, and switching between the ongoing and PM activities. Although PM involves similar cognitive mechanisms to episodic future thinking and retrospective memory, such as encoding and retrieving information over time, it contrasts with standard episodic or working memory. This is because PM depends not only remembering “when” to remember, but also on correctly remembering “what” should be remembered and “how” that information should be acted on. Although PM cannot be regarded as “process pure” because of the many cognitive functions it involves, it is a multiprocess framework drawing on a specific combination of processes that distinguish it as a unique type of memory with dissociable functions that balance automatic and strategic cognitive mechanisms (see McDaniel and Einstein 2000; Ball and Aschenbrenner 2018).

The most commonly investigated PM processes focus on time-based or event-based remembering. Time-based PM is centered around time-sensitive remembering, such as attending an appointment at 2:00 p.m. next Wednesday or turning off the oven after 30 min. Accordingly, time-based PM depends on self-monitoring and effective internal time-keeping to perform the PM action at the appropriate time. It also relies on self-

regulated inhibition to stop an ongoing activity so that the PM action can be completed. Therefore, time-based PM places substantial competing demands on cognitive resources (Ball and Aschenbrenner 2018). By contrast, event-based PM involves remembering to carry out an intention in response to an external cue or event, such as taking medication with breakfast or posting a letter when you pass the post office. Often, supportive strategies, such as using a diary or memo note, are helpful in serving as reminders or cues. Additionally, event-based PM can be prompted by other events or circumstances that occur simultaneously. For instance, seeing a postbox might serve as a reminder to post the letter. In this way, event-based PM can be considered less demanding on executive functioning/working memory processes.

The effective use of PM is vital for everyday functioning, autonomous living, and self-management of one's healthcare and daily living skills (e.g., remembering to take medication; pay bills on time; or attend an appointment next week). It is also a primary reason for everyday forgetting and is one of the most sensitive factors in age-related cognitive decline (Woods et al. 2012). Previous research has shown variable PM performance in typically developed individuals, depending on the types of tasks and PM cues (e.g., routine/non-routine; regular/irregular; important/not important; focal/non-focal), depending as well as on the valence of cues, and cognitive load of any ongoing tasks (e.g., Ball and Aschenbrenner 2018). In the context of ageing, PM ability depends on the context of the task and whether it is carried out in a naturalistic environment or laboratory-type setting. In particular, research has shown that older typically developed adults tend to perform as well as younger adults on event-based tasks, but have greater difficulties on time-based tasks (mirroring the performance seen in autism; see below). By contrast, in naturalistic settings, several studies have observed the reverse pattern of abilities (see Henry et al. 2004 for a review). In turn, PM failures are closely linked with increased cognitive decline in older age and poor physical and mental health.

Consequently, research suggests PM ability underpins the ability to function well, with abilities also predicting health-related quality of life, particularly in older age (Woods et al. 2012).

Prospective Memory and Autism

Individuals with autism spectrum disorder (ASD) demonstrate a unique profile of cognitive strengths and difficulties. A large body of research suggests a profile of impairments in autism that includes some aspects of executive function (e.g., inhibition of prepotent responses, complex planning), as well as difficulties recalling memories of personally experienced past events (episodic recollection), particularly on tasks that involve self-initiated recall of information (Bowler et al. 2015). However, relatively few studies have explored PM abilities in ASD and little is known of how PM contributes to everyday functioning and quality of life of autistic individuals (see Roestorf 2018).

In general, studies have explored distinctions between event-based and time-based PM in ASD, with varied findings, depending on task type and PM function (see Landsiedel et al. 2017 for a recent review). One difficulty with interpreting some studies of PM ability in autism is that several studies have assessed both event-based and time-based PM abilities concurrently, in the same task. This is problematic, as impairments in one type of PM may well confound performance on other aspects of the task (see Landsiedel et al. 2017 for a wider discussion). However, when PM abilities are examined in studies that assess time-based and event-based performance in separate tasks, results suggest that autistic individuals have difficulties completing time-based PM tasks in particular (e.g., Williams et al. 2013, 2014). By contrast, impairments on event-based PM tasks appear considerably smaller in autism. In general, time-based PM ability in autism seems largely related to executive function ability, and one possible explanation for this pattern of PM abilities is that more general impairments in executive function in autism seem to broadly underpin difficulties on time-based PM

task. This is likely a result of time-based PM relying more heavily on monitoring and self-initiated retrieval of PM intentions, both of which place high demands on executive function, whereas the executive loads posed by event-based tasks is considerably less, as event-based PM is typically supported by cued retrieval. Alternatively, poor time-based PM performance may also be the result of diminished self-projection ability (see Lind et al. 2014) and impairments in episodic future thinking (see Williams et al. 2013, for a wider discussion).

Recent research exploring PM abilities in both laboratory and naturalistic settings (Roestorf 2018) has also suggested that, whereas younger autistic adults presented similar difficulties to those observed in older typically developed adults (demonstrating greater impairments on time-based tasks than event-based PM tasks), this was not the case for older autistic adults. By contrast, older autistic individuals demonstrated more accurate PM abilities in event-based and time-based tasks in both laboratory and naturalistic settings, compared to matched typically developed adults. Overall, these findings present an emerging picture of PM function in ASD and suggest that PM difficulties may present different challenges for autistic adults at various life stages. However, substantially more research is needed to understand developmental influences on PM and how individual differences in time-based and event-based PM affect everyday functioning and quality of life in autistic individuals across the lifespan.

Protection and Advocacy System (P&A)

Susan Luger
Susan Luger Associates, New York, NY, USA

Synonyms

[Client assistance program](#)

Definition

The Protection and Advocacy (P&A) System is comprised of a nationwide network of organizations that has been mandated by the Congress to protect and advocate for the rights of people with disabilities. These organizations provide legal representation and other advocacy services. The goal of P&A is to provide people with disabilities, including children and adults on the autistic spectrum, equal access to employment opportunities, education, public services, healthcare, housing, and public accommodations. P&A organizations investigate abuse, neglect, and barriers that prevent disabled people from becoming productive and independent members of their community. Protection and Advocacy agencies are located in every state and are the primary nonfederal enforcers of disability rights statutes. These organizations may be part of the government or private not-for-profit organizations.

Protodeclarative

Cheryl Smith Gabig
Department of Speech, Language, and Hearing Sciences, Lehman College/The City University of New York, Bronx, NY, USA

Synonyms

[Comment](#); [Communicative act](#)

Definition

A primitive speech act used to establish social interaction and direct a caregiver's attention to an object, action, or entity. It is referred to as a protodeclarative because the directed attention to an object, action, or entity by the child acts as a comment in a communicative exchange. A protodeclarative may take several gestural forms including pointing to, showing, or giving of objects. The gesture may or may not be accompanied by a ritualized vocalization. The protodeclarative appears in typically developing children between 8 and 9 months of age. It is thought to demonstrate a shift in cognitive-linguistic development in that its use reflects the child's conscious intent to initiate social interaction and establish joint attention to an object, action, or entity with a caregiver.

Children with autism engage less often in the intentional use of protodeclarative gestures such as pointing, showing, and giving, meant to establish or maintain social interaction and joint attention. There is evidence that the lack of intentional

communication and bids for social interaction are related to a failure of various underlying mechanisms supporting development of preverbal communication.

- may take the form of a vocalization, a conventional gesture, or a combination of both. The protoimperative, as a ritualized request, appears in typically developing children between 8 and 9 months of age and is thought to demonstrate a shift in cognitive-linguistic development in that its appearance reflects the child's conscious intent to communicate to the caregiver to act as an agent to attain an object or perform an action. The protoimperative often takes the form of a pointing gesture or a whole-hand or swiping motion toward the desired object, frequently accompanied by a ritualized vocalization, such as a whine or grunt. Eye contact is usually established between the child and the caregiver during or following the ritualized request act. The intentional gestural communication and vocalization occur away from the object or action and are considered to be distal in nature.
- Children with autism frequently do not develop a protoimperative communicative function characterized by the use of distal communicative gestures, such as pointing while vocalizing. Rather, a request function may be accomplished via a contact gesture, such as leading a caregiver by the hand toward the desired object/action, or placing the caregiver's hand on the object. Protoimperatives using distal signaling via conventional gestures, vocalizations, and eye contact are often absent.

Protowords

Andrea McDuffie
MIND Institute University of California-Davis,
Sacramento, CA, USA

Synonyms

Phonetically consistent form; Quasi-words;
Vocable

Definition

Protowords are word-like forms produced by young children as they transition from prelinguistic to linguistic communication (i.e., the time at which children produce intelligible single words that approximate conventional pronunciation). In typical development, protowords emerge between 10 and 12 months of age and are made up of the types of sounds that children use when babbling. Common examples of protowords are mama, dada, and baba. Protowords differ from repetitive babbling in two critical ways: (a) protowords are limited to one to two syllables in length and (b) protowords are used consistently by the child to refer to a corresponding object, person, or event in the child's immediate context. Protowords also have been referred to as repeatedly occurring phonetic units loosely bound to specifiable contexts.

Protriptyline

Lawrence David Scahill
Nursing and Child Psychiatry, Yale Child Study
Center, Yale University School of Nursing, New
Haven, CT, USA
Marcus Autism Center, Children's Healthcare of
Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University,
Atlanta, GA, USA

Synonyms

Vivactil

Definition

Protriptyline is in an older class of antidepressants known as tricyclics. The term “tricyclic” refers to the three-ring structure of this class of antidepressant medications. These medications are not used as commonly as in the past as they have been largely replaced by the SSRIs. Protriptyline is predominantly a norepinephrine reuptake inhibitor.

The tricyclic antidepressants have several adverse effects in common including dry mouth, urinary retention, constipation, nausea, increased heart rate, dizziness, and, at higher doses, confusion. The tricyclic antidepressants also carry some risk of altering the electrical conduction in the heart. They are well known to be fatal on overdose due to their potential for causing cardiac arrhythmia. Because of their known toxicity at higher doses, treatment with tricyclic antidepressants

requires blood-level monitoring and electrocardiogram monitoring as well. Finally, the tricyclic antidepressants are also vulnerable to drug-drug interaction. For example, some medications such as SSRIs or certain antibiotics may interfere with the breakdown of tricyclic antidepressant medications. The interference of metabolism of the tricyclic can cause a sharp increase in the blood levels of the tricyclic antidepressants and increase the vulnerability to toxic effects. The tricyclic medications have not been well studied in children or adults with autism.

Provider Training

Jacqueline Kelleher
Education, Sacred Heart University Isabelle
Farrington School of Education, Southern
Connecticut State University, Fairfield, CT, USA

Definition

Provider training is the professional development or technical assistance offered to or participated in by providers to develop competencies and proficiencies on a particular topic or in a specific area necessary for ensuring services, supports, and programming are delivered appropriately and

with fidelity. Provider training often includes a variety of topics, such as the characteristics of autism (including diagnostic, cognitive, sensory, and attentional features), functional assessment (including behavior and adaptive skills), instructional strategies (including applied behavior analysis or ABA techniques such as discrete trial training, structured teaching, and incidental teaching), data collection, teaching functional communication and social skills development, and transitioning into employment settings. Provider training also extends to higher education and other agencies preparing preservice professionals.

A provider is someone whose business is to supply a particular service or commodity or a person or group of people who plans and delivers a program. In the area of autism, providers may include but are not limited to the following domains: health care (medical, dental, physical, mental health, pediatric), special education, related services, school personnel, developmental services, rehabilitation, birth to three, community-based staff, post-secondary disabilities units, developmental specialists, and parents or legal guardians. Further, federal requirements under the Individuals with Disabilities Education Act call for qualified providers in the area of special education and related services. Related service providers can include, in addition to the aforementioned areas, professionals in audiology, early intervention, physical/occupational therapy, speech-language pathologists, recreation, school health/nursing, and social work. Providers can deliver direct services, usually referring to hands-on interactions between the provider and client or student, or indirect services, which may involve consulting with or supervising other staff in the delivery of services.

Historical Background

Though *ASD* is a familiar term in the early twenty-first century, it was only recognized in the 1940s as a severe disability. Since that time, there has been extensive interest in and professional activity concerning autism.

Current Knowledge

It is well understood among the experts developing and delivering provider training in the area of autism spectrum disorders that those receiving the training are prepared on the nature of *ASD* (etiology, incidence, range of symptoms, possible medical concerns), early identification, intensive programming, comprehensive curricula, systematic instruction, objective assessment, providing structured and predictable environments, delivering evidence-based practices and interventions for *ASD*, strategies and tools for implementing best practices across a multitude of settings (classroom, home, workplace, community, etc.), transition planning, and knowledge of facilitating peer relationships. Moreover, providers need to be familiar with terms and definitions used by professionals and consultants developing programs and supports in other service areas in order to best plan for and support the individual with *ASD*.

School-based personnel need training in understanding the characteristics of *ASD* and providing supports for individuals with the disorder. Further, it is recommended that school administrators should understand the educational needs of students with Autism so they can provide a quality program using a variety of service delivery models for children across the age span. Students with autism benefit from individualized and often intense educational services beginning early in life, services that require specialized training for those providing educational interventions with the following characteristics: (1) behaviorally based; (2) carefully planned and monitored instruction involving task analyses of skills, individualized incentives, goals embedded in routines and activities, and adequate intensity and quality; (3) ongoing, planned opportunities for interaction with typical peers; (4) need-based supports and intervention for families; (5) services delivered in many different settings to meet support needs and promote generalization; (6) broad curricular content that addresses all developmental needs; and (7) proactive use of positive behavior support for challenging behavior. Children with autism typically require the services of special educators,

general educators, and speech and language pathologists; occupational or physical therapists often address children's movement and sensory limitations. A collaborative team approach is necessary to plan, problem-solve, implement, and monitor the individualized education programs (IEPs) of these students; as part of a collaborative team, those participating on behalf of an individual with *ASD* should receive training in how best to support the individual with *ASD* given deficits in the areas of communication, behavior, and social interactions.

In the area of early screening for *ASD*, clinicians engaged in developmental screening in health care, community, and school settings are in a unique position to promote children's developmental health, and the Centers for Disease Control strongly suggests clinicians participate in training through the American Pediatric Association in the importance of early childhood development, early intervention, the screeners, appropriate referrals, and billing information; clinicians, in turn, should train other staff and personnel in the practice, particularly in using the screening instruments. Other service providers who may or may not be a part of an individual's educational team require training in how to meet the needs of people with *ASD* in a variety of areas and settings including:

- Consultation for families, educators, and service providers
- Evaluations for eligibility determination
- Training for supporting professionals and families
- Treatment planning and planning for families
- Service coordination
- Early intervention services
- Genetic evaluation, treatment, and counseling services
- Stipends for day care (through ABC block grant) and transportation

- Prescribed drugs
- Private vehicle modifications
- Psychological services
- Respite care
- Specialized medical equipment, supplies, and assistive technology

Future Directions

Numerous legislative blue-ribbon commissions and statewide needs assessment initiatives are adding to the literature on the dissemination and implementation of best practices. In the 2008 session, the Connecticut General Assembly passed Special Act 08-5, *An Act Concerning the Teaching of Children with Autism and Other Developmental Disabilities*, and legislated a study group comprised of designees from four state agencies to complete an assessment of school-based personnel needs regarding service delivery to this population of learner and their families. The study group gathered, analyzed, and interpreted new and existing data from seven public forums, three online surveys, policy documents, and information from state data systems to generate recommendations and assemble a statewide plan addressing the methods of teaching children with autism in accordance with requirements of the Act. Findings included several themes confirmed by other states in their own investigations of provider needs including inconsistent quality assurance procedures for ensuring existing statewide training opportunities provided to school personnel and families reflect evidence-based practices, specifically around content, delivery, expertise, results, and alignment with national ASD competencies. Another example is the California Task Force on Education and Professional Development which delivered a set of best practice guidelines for those serving persons with ASD concerning the design and delivery of effective programs as well as a credentialing system for preservice professionals and teacher aides seeking

to work with children and youth with ASD in educational settings. Further, California has proposed that all teachers, including general educators, receive training in ASD as part of their preparation programs. The Alabama Autism Task Force and the University of Alabama Birmingham listed provider training as a top priority in its 2008 statewide assessment across agencies serving individuals from birth through adulthood, covering screening and early intervention through supportive employment opportunities. The Pennsylvania Department of Public Welfare and its state autism task force made training a top priority for its Bureau of Autism Services and has instituted a free, online virtual training site/resource center for its providers in state in order to build capacity across all regions. Many states are beginning to develop and/or implement community and direct service provider trainings tailored for staff involved in autism insurance waiver programs. Waiver provider trainings in most states supporting this effort include focuses on supports coordinators, level of care assessors, behavioral specialist interventions, individualized service plan development, and navigating systems of care. Additionally, several states are reviewing and revising state statute regarding language around coursework or training necessary for providers in meeting the needs of individuals with ASD as well as for those delivering training to the providers across multiple areas.

Definition

Fluoxetine is a selective serotonin reuptake inhibitor (SSRI) commonly used to treat major depressive disorder (MDD), obsessive-compulsive disorder (OCD), bulimia nervosa, panic disorder, and premenstrual dysphoric disorder (PMDD), among other disorders (Wenthur et al. 2013). Some research suggests that fluoxetine can be used to treat repetitive behaviors in individuals with autism spectrum disorder (ASD); however, findings are inconsistent and placebo-controlled studies are scarce (Accordino et al. 2016).

Fluoxetine (molecular formula: $C_{17}H_{18}F_3NO$) is an oral formulation commonly known by the brand name Prozac. It was discovered by Eli Lilly and Company in 1972 and was the first SSRI to be approved for medical use by the United States Food and Drug Administration (FDA) in 1987. The introduction of fluoxetine represented a medical breakthrough in the treatment of depression and offered greater efficacy and lower side effects compared with tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). Indications for fluoxetine include adult and pediatric major depressive disorder, adult and pediatric obsessive-compulsive disorder, premenstrual dysphoric disorder, panic disorder, and depressive episodes in bipolar I disorder. Common side effects of fluoxetine include sexual dysfunction, nausea, headache, drowsiness, diarrhea, weight loss, and tremors. Individuals taking fluoxetine also may experience increased risk of suicidality, violent thoughts or behaviors, and aggression (Wenthur et al. 2013).

Selective serotonin reuptake inhibitors (SSRIs) block the reabsorption of serotonin (5-hydroxytryptamine; 5-HT) neurotransmitters in the brain, causing increased levels of serotonin to be available. Some researchers hypothesize that serotonin dysregulation plays a role in the pathophysiology of ASD. According to this theory, dysregulation of serotonin in early periods of development leads to cortical abnormalities and alters neurotransmission of serotonin (Hollander et al. 2012). Additionally, the similarities in clinical presentation between compulsions in OCD (for which SSRIs are a first-line treatment) and

stereotyped behaviors in ASD lead some researchers to believe SSRIs could be used in the treatment of ASD (Accordino et al. 2016; Hollander et al. 2012).

Currently, no medications are approved by the FDA for the treatment of the core symptoms of autism spectrum disorder (Hollander et al. 2005). However, some research suggests that fluoxetine may be used as a treatment to reduce restricted and repetitive behaviors (RRBs) in individuals with ASD. Open-label and retrospective studies generally suggest SSRIs may be successful in treating some symptoms of ASD in both adults and children (Accordino et al. 2016; Hollander et al. 2005). However, few placebo-controlled trials have been undertaken (Accordino et al. 2016).

Studies of SSRIs have shown significant improvements in adults with ASD. Currently, there is only one published double-blind placebo-controlled study exploring the use of fluoxetine for adults with ASD. In this study, researchers examined the use of fluoxetine to treat repetitive behaviors in 37 adults diagnosed with ASD. Hollander and colleagues found that – compared with placebo – individuals given fluoxetine showed greater improvement in repetitive behaviors on the compulsion subscale of the Yale-Brown Obsessive Compulsive Scale (Y-BOCS), on the obsessive-compulsive symptoms rating on the Clinical Global Impression (CGI) scale, and on the CGI rating of overall improvement. Participants received a moderately high dose of fluoxetine (mean dose 64.76 mg/day) over the 12-week trial and experienced only mild or moderate side effects (Hollander et al. 2012). A placebo-controlled study of a different SSRI, fluvoxamine, for adults with ASD also found significant improvements in a variety of symptoms, including repetitive thoughts and behaviors, language, and maladaptive behaviors (Accordino et al. 2016).

Placebo-controlled trials of SSRIs in children have shown inconsistent results. Unlike findings with adults, a study of fluvoxamine for children with ASD showed low tolerability and a low success rate (only 1 in 18 participants showed improvement in target symptoms). Additionally, in a large-scale placebo-controlled study of the SSRI citalopram, children with ASD showed no

difference in improvement between the SSRI and placebo. While placebo-controlled studies of fluvoxamine and citalopram have not found positive results in treating children with ASD, some research supports the use of fluoxetine for children with ASD. A study exploring the use of low-dose liquid fluoxetine found the medication to be successful in treating repetitive behaviors in children and adolescents with ASD. In this placebo-controlled crossover trial, 45 children with ASD were randomized and 39 participants were included in the analysis. At the end of the 8-week treatment period of low-dose fluoxetine (mean final dose 9.9 mg), children showed improvement in repetitive behaviors as measured by the compulsions subscale of the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) with a moderate to large effect size (Hollander et al. 2005). However, an unpublished multicenter placebo-controlled study examining the use of fluoxetine to treat repetitive behaviors in 158 children with ASD found no significant improvements when compared with placebo. Some researchers suggest that the differences in efficacy and tolerability of SSRIs in adults versus children with ASD may be due to changes in serotonin functioning throughout development (Accordino et al. 2016).

Definition

Pseudoscience is a term used to describe proposed theories and therapies that are described as evidence based but actually have limited or no scientific support. Examples of therapies for autism

whose proponents describe them as scientifically based, but, in the judgment of most experts, are currently not supported by scientific evidence include the following: biofeedback/neurofeedback, “energy” therapies, animal-assisted therapies, electroconvulsive therapy, withholding vaccinations, and facilitated communication (Thyer and Pignotti 2010). Other such therapies are elimination diets, vitamin therapy, and anti-yeast therapy. The evidence provided to support these therapies meets many of the criteria listed below, which can serve as red flags for recognizing pseudoscience:

- *Rationale or underlying theory is not based on existing data* (Lilienfeld 1998): The intervention is not connected to other bodies of scientific knowledge and does not build upon existing research. A treatment may be pseudoscience if it is recommended without research that points to a link between the variable being manipulated (e.g., yeast, vitamins, gluten, etc.) and the symptoms of autism. In place of this research, the authors of pseudoscience may instead use complicated, scientific-sounding language to explain why the intervention works.
- *Reversed burden of proof* (Lilienfeld 1998): Scientists typically place the burden of proof on themselves. That is, if they propose a relationship, it is their responsibility to try to find evidence to support this relationship. Pseudoscientists may place the burden of proof on others and require someone else to prove that the relationship *does not* exist. For example, proponents of anti-vaccination insist that others refute the hypothesis that autism is linked to vaccines.
- *When studies have been done, they suffer from methodological weaknesses* (Offit 2008): Strong studies will have multiple levels of control including large sample sizes, random assignment, and isolation of a single variable, while other variables are held constant. These characteristics make the results of a study more reliable. Studies without these levels of control that lead to generalizations and unqualified conclusions may be pseudoscience.
- *Reliance on anecdotal evidence and testimonial* (Offit 2008): Instead of referring to clinical trials as evidence that their interventions work, proponents of pseudoscientific interventions often give anecdotal examples of children and families treated with great results. Aside from the obvious problem of verifying these testimonials, anecdotal reports are problematic because the effects of an intervention on one child cannot be generalized to the entire population of children and adults with autism. Additionally, without isolating a single variable, there is no way to attribute improvement to the intervention. Improvements may be explained by another therapy or by normal growth and maturation.
- *Overinterpretation of results* (Offit 2008): At this time, there is no single known cause or cure for autism. An intervention that is touted as a “cure” or describes “recovery” may be pseudoscience. Additionally, the causes of autism are numerous & complex, a study singling out one “cause” of autism, without reference to complex and interacting factors should raise a red flag.
- *Results have not been replicated; replications may be difficult or impossible* (Offit 2008): Offit warns against reacting to a single study, especially if the study is the first of its kind or “appears to break new ground.” A reliable intervention will be supported by many studies replicating the same positive results. Furthermore, a good study will have a detailed methods section, allowing other researchers to replicate the study. Vague descriptions of the methods may prevent replication and indicate pseudoscience.
- *Unchanged by disconfirming research* (Bunge 1984): Although the original study that led to a proposed relationship between autism and vaccines has been discredited and several large studies have found no link, many anti-vaccination proponents continue to believe in the relationship. Similarly, specific

interventions (e.g., elimination diets) may still be encouraged after several studies fail to find evidence for their support.

- *Conflict of interest* (Offit 2008): Most peer-reviewed journals require authors to report funding source and potential conflicts of interest. An example of a conflict of interest is a scientist receiving income from a drug company to show that a drug manufactured by that company is effective; the scientist's financial interest (i.e., income) may compete with his scientific interests and cause falsification or omission of data. Another example is an intervention that requires families to pay for a product or service, outside of an established medical or educational system.

Psychiatric Problems and Care in Older Adults with Autism

Lena Nylander

Department of Psychiatry, Clinical Sciences,
Lund University, Lund, Sweden

Although autism spectrum disorders (ASDs) are often conceived as lifelong disabilities, little is known about their impact on individuals, families, and society as the affected persons grow old. Research in ASD is still only seldom concerned with middle-aged or older people. There are several follow-up studies showing that these disorders, which in all cases are present at an early age, are relatively stable from childhood to adolescence, and, especially if accompanied by intellectual disability (ID), into adulthood. Although two studies of the same Swedish cohort with normal IQ ASD ($n = 47$) showed that “caseness” slowly diminished (Helles et al. 2015), at mean age 30 years 76% still met criteria for an ASD.

In a review of 23 follow-up studies, Howlin and Moss (2012) found that the adult outcome of ASD in individuals with IQs in the normal range was described as unfavorable in the majority of cases. Only two of the 23 studies in the Howlin and Moss review comprised any individuals older than 50 years, and the larger part of all research in ASD is still conducted on children. Thus very little is known about ASD in people older than around 50 years (Bennett 2016), and only recently has work been commenced in this area, primarily in the UK, the USA, and the Netherlands. However, the knowledge concerning this group is still very limited, and there are many unanswered questions concerning the prevalence of ASD in these age groups, symptom persistence and variance, life circumstances and quality of life, concomitant illness and disorders, as well as services and care needs. It can be assumed that ASD in older adults to a large part is undiagnosed, since there is little reason to believe that the

PSI Test

- [Pediatric Speech Intelligibility Test](#)

prevalence of autism in older adults is much lower than 0.5–1% – the lower number if the Swedish follow-up studies mentioned above is taken into account (Brugha et al. 2011; Helles et al. 2015).

In the most recent years, ASD advocates have been pointing to the scarcity of knowledge concerning autism and aging, and efforts have been made to elucidate the problem. Several studies concerning neuropsychology, for example, by Dutch researchers, have been made. Other authors have investigated concomitant somatic and psychiatric diagnoses and use of services and care. These latter studies are usually made as register studies, with the pros and cons that are inherent to this methodology.

A number of nationwide register studies comprising a cohort of all Swedish elderly (born 1957 or earlier) community service users with intellectual disability (ID) and/or ASD have recently been made by Swedish researchers (Nylander et al. 2018). Of all registered individuals ($n = 7936$), the number with ASD diagnoses was 601, 64% males and 36% females. Concomitant ID diagnoses were registered in 256 cases. Fifty percent of the ASD group had any other psychiatric diagnosis, most often affective or anxiety disorder, and 63% had been in contact with specialist psychiatric care during the 10 years studied. Male gender, concomitant ID, and especially an Asperger syndrome diagnosis raised the OR for psychiatric care. Prescriptions of psychotropic drugs, in particular antipsychotics, were very common (more than 70%, in contrast to 12% having a diagnosis of psychotic disorder), and 24% had four or more psychotropic medications.

In summary, the so far scarce research into ASD in the elderly suggests that ASD is underdiagnosed and probably under-recognized in many cases and that older adults with ASD, or at least some of them, are a vulnerable group whose needs may be unmet.

A Swedish psychologist who made a pioneering work interviewing a group of elderly persons with ASD found that some of them expressed gratefulness for not having been diagnosed and “interfered with” when they were children. This implies that we should be careful to see the person and not only the diagnosis and,

consequently, offer only services that are wanted by the person and which we are certain would make a positive difference.

Psychiatrist

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

A physician specializing in the evaluation and treatment of mental disorders. In the USA and Canada, these specialists have received M.D. or

D.O. degrees. Following specialty training, board certification is available in general psychiatric and a variety of subspecialties including child and adolescent psychiatry. The latter group often has the most experience with individuals with disabilities (of all ages), and all child and adolescent psychiatrists in the USA have received training in adult psychiatry as well. Forensic psychiatrists specialize in work with courts and the legal system. Training systems differ somewhat in other countries. Psychiatrists work to evaluate, diagnose, and treat a range of disorders with a range of methods including pharmacological (drug) and other treatments. For individuals with autism, a variety of comorbid psychiatric conditions may require such treatment, and a handful of medications have now been specifically approved for use in autism. These individuals also have special expertise in working with other medical professionals around other conditions the individual might exhibit, and this can be particularly important in situations where the person exhibits a medical problem with behavioral aspects such as epilepsy. It is important that the psychiatrist has experience in the evaluation and assessment of individuals with autism (Ghaziuddin et al. 1992; McCracken et al. 2002; Scahill and Martin 2005; Tuchman and Rapin 2002).

[Psychoanalyst](#)

Definition

Psychoanalysis

In their classic book on the *Language of Psychoanalysis*, Laplanche and Pontalis define psychoanalysis as a therapeutic approach developed by Sigmund Freud with a characteristic method of investigation (“free association”) that Freud claimed identified emotions and emotional conflict in the psychoanalytic relationship, a theory that attributes experience and behavior to conflicts between emotional impulses or instincts of which we are not directly conscious and the efforts that we make to block them from influencing us, and a psychology that is based on the theory and justified by the investigative method.

Psychodynamics

The psychology developed within psychoanalysis has also been called dynamic psychology, or psychodynamics. A basic premise of psychodynamics is that actions and reactions need energy and that this is derived from a well of energy, or drive, of which a person is not directly conscious or, as psychoanalysts would say, that are “in the unconscious.” These drives, like the hot fluids from the earth’s mantle, may break through a crust of repression and come into the light of consciousness,

albeit changed. An easy and nondisruptive discharge of this energy on a social appropriate object is healthy: blocked discharge or a discharge that causes damage through its force or its trajectory is unhealthy. Psychodynamic theories of autism are therefore based on the vicissitudes of drive energy supplemented in the post-Freudian era by energy arising from a new source (corresponding to a more recent theory of motivation) – the need for another person.

Freud originally supposed that it was sexual desire that was the most important drive (at least in people who were not starving or parched with thirst). So his psychodynamics concentrates on the vicissitudes of sexual desire during development. The open expression of sexual desire is inhibited by the primary carer, he thought, at least until the child develops some personal awareness (Freud attributes this to the creation of an “intrapsychic structure,” the Ich; Lacan calls this a new order of representation, l’Imaginaire, ushered in by the growing awareness of the father) and later some social awareness (again, attributed to an “intrapsychic structure,” the uber-Ich; Lacan calls this order, le Symbolique, and considers that it is ushered in by the name of the father). Freud supposed that there was sexual desire from birth, but at birth, it was directed toward the baby’s own skin. This development is easily derailed and so fails to develop normally, getting stuck or “fixated.” Early derailment was supposed to be associated with psychosis (no evidence was given for this assertion nor for the apparently normal development of people who developed psychoses in adulthood). Lacan thought that normal development required the acquisition of the name of the father, i.e., of the “name of the father,” and that a failure to acquire this led to a persistent susceptibility to imaginary rather than symbolic representation.

Lacan’s theory seemed to provide a neat explanation of the lack of language development in children with Kanner’s syndrome although it was not clear why it did not also apply to children who were normally socialized but had severe speech and language disorder. Freud’s theories were equally facile, but this time, in explaining the touching, sucking, poking, and self-stimulatory stereotypies associated with children

with Kanner’s syndrome. Again, it was not explained why it applied so well to children with intellectual disability and neglected children if it was to be a theory of ASD.

Autoerotic

The earliest phases of emotional development were the ones linked by Klein, a follower of Freud, to “psychosis” (never a clearly defined term in psychoanalytic literature) and to autism, which was considered to be a kind of psychosis. Freud had termed the earliest phase of sexual development when the infant was supposed to be erotically gratified by its own body, “autoerotic.”

“Autism”

Bleuler had, like Sigmund Freud, studied with Charcot, at Salpêtrière. He wrote a favorable book review (Bleuler 1896) of the monograph by Freud and his mentor Breuer that described their use of the hypnotic method to treat anxiety-related disorders and which launched psychoanalysis as a treatment. His assistant, Jung, and he had corresponded with Freud and had devised a word association experiment to test Freud and Breuer’s theory of repression which led Jung to formulate the concepts of “complexes,” for words that were delayed in recall, as against “simplexes” which were repeated with minimal delay. Bleuler moved away from Freud from about 1911 on, just after the publication of his textbook in which he introduced the word “autism” to a wider audience (Bleuler 1911). Bleuler gave his reasons for the distance in 1913 (Bleuler 1913), but he remained supportive of psychoanalysis, and in 1914, Freud could cite him (Freud 1914) *as an influential sympathizer*: “After this it was impossible for psychiatrists to ignore psycho-analysis any longer. Bleuler’s great work on schizophrenia (1911), in which the psychoanalytic point of view was placed on an equal footing with the clinical systematic one, completed this success” (Bleuler 1911, p. 28).

The term “autism” was coined by Bleuler in 1907 and was derived from Freud’s term “autoeroticism.” Freud wrote to Jung (Freud and Jung 1974) that “Bleuler still misses a clear definition of autoeroticism and its specifically psychological

effects. He has, however, accepted the concept for his Dem[entia] pr[aecox] contribution to Aschaffenburg's Handbook. He doesn't want to say autoerotism (for reasons we all know), but prefers 'autism' or 'ipsism'" (Freud and Jung 1974, pp. 44–45).

What Freud's correspondents would "all have known" is now forgotten, but there was no doubt that Bleuler used the word "autism" knowing that it implied a psychological cause for schizophrenia. Indeed, his treatment method, and that of his son, Manfred, attempted to link the psychological approaches of Freud and Jung with the organic approach of Kraepelin.

Historical Background

The psychoanalytic roots of the autistic spectrum disorders (ASDs) lie in the development of schizophrenia, or rather of dementia praecox, at the end of the nineteenth century and some 40 years before ASD was first described. That century had seen a conflict between the Romantic view of psychiatric disorder that attributed it to hidden mental problems and the organic approach that attributed it to pathological changes in the brain (Ellenberger 1970). It was widely recognized in the nineteenth century that the reasons for many actions were "unconscious" but determined by learned associations (Thomson 1964). The Romantics sought to correct these associations by rewards and punishments, believing that in this way mental illness could be cured. Paradoxically, this could lead to the development of coercive treatment that was often cruel and abusive, although not always. Samuel Gaskell, physician superintendent of Lancaster Moor Hospital in the UK, gave "disappointment in love" as the most common reason for admission of women to the asylum but also advocated conditions that would enhance the dignity and autonomy of his patients as much as possible (Tantam 1990).

The same paradox has reasserted itself in ASD a century later, where expectations of cure have sometimes led to cruelty and harm, although this has not been restricted to the proponents of a psychological cause for ASD.

The opponents of the Romantic approach, the biological psychiatrists, were much more negativistic, believing that mental illness was due to degeneration of the brain, with a number of them concluding that this degeneration was both hereditary and progressive. Enlightened biological psychiatrists thought that as their patients were incurable, they should be given the conditions most likely to mitigate their condition. This could be interpreted benignly, as it was by Gaskell, but also led to the development of the "institutions" where people were simply sequestered with minimal attention to their health and safety, and none to the possibility of recovery. Institutions became a byword for neglect, environmental poverty, and a lack of social stimulation that contributed so much to the clinical presentation of older children and adults with an ASD who had been "kept" in these conditions. However, there was an alternative approach that stressed what we would now call "normalization," but would then have been called "moral treatment."

In the midst of this confusion, it was difficult to make any scientific progress on which treatments worked for who – if any did – or what the course of a person's particular condition or problem would be. Griesinger, the father of the biological psychiatry approach, pinned his faith in pathological studies of the brain and that proved well founded for "general paralysis of the insane" a psychosis caused by syphilitic infection. But the pathology of other psychoses, the so-called functional psychoses, remained elusive, as it does today.

Again, there are parallels with ASD. There are some genetic conditions that are known to have a high risk of conferring ASD, and the neuropathology of these is increasingly well understood. But the pathology or pathologies characteristic of most of the ASDs remain obscure. As a result, the future of an individual with an ASD, and therefore knowing what would best help that person, remains unclear.

Emil Kraepelin's answer to this situation was to undertake a kind of case-control study, selecting the records of patients with a poor outcome and comparing previous notes made of their presentation and course with those in the records

of patients with a good prognosis to see if there were features that could predict the outcome. He coined the term “dementia praecox” for this group, a term that did not find favor in the UK or the USA. Anglophone psychiatrists accepted Kraepelin’s concept of the remitting “manic-depressive” psychoses but thought that Kraepelin had been too nihilistic about the other group of functional psychoses, for which they much preferred Eugen Bleuler’s term “schizophrenia,” introduced by Bleuler in 1911 (Bleuler 1911).

It is at this point that the history of psychoanalysis begins, as well as the history of the term “autism” which psychoanalysis inspired.

Current Knowledge

Kanner, in applying Bleuler’s term “autism” to children in 1944, did so knowing that it evoked a psychological causation. But by this time, Freud’s specifically sexual description of infant development, and the centrality of the vicissitudes of sexual energy or libido, had changed with the impact of Melanie Klein and the object relations theorists. She had, confusingly, adopted a term developed by the Scottish psychoanalyst and medical anthropologist Fairbairn – “schizoid” – to describe the stage of development shortly after the stage that Freud called “autoerotic.” This term had also replaced “autism” in the second edition of Bleuler’s textbook on schizophrenia. It is not clear whether Bleuler read Fairbairn, or Fairbairn read Bleuler. Bleuler’s textbook was only translated into English in the 1950s, and Fairbairn’s only published in the 1950s, too although he had given his paper about schizoid personality in the 1920s. But the shared etymology – both are derived from the ancient Greek for split – suggested to many commentators that there was a fundamental connection.

Muddying the Waters: Schizoid Personality, Autism, and Schizophrenia

Inferring a connection of things from their resemblance has a long history in medicine. The use of mandrake (*Mandragora* sp.) as a “sympathetic” treatment comes, for example, from its forked root

that was said to resemble a pair of legs. Mandrake looked to the credulous eye like a homunculus and so was assumed to have some human qualities (see, e.g., the references to it “screaming” when uprooted in the Harry Potter novels). Freud himself characterized such metaphorical or “iconic” reasoning to be characteristic of “the hysteric” and the dreamer (Freud 1965), but it has been a fallacy into which many psychoanalytic theorists have slipped.

The resemblance of autism in schizophrenia and early childhood autism created a connection between the two that led to ASD being rechristened early childhood schizophrenia for a number of years. Although some research groups do identify childhood-onset schizophrenia in children as young as age 7, they also consider that there are key symptoms can distinguish between the two and that the outcomes are different. So more narrowly defined schizophrenia and autism do not overlap, as Kanner indicated in his first description although they may occur together.

Psychoanalysts might also refer to schizophrenia but on the basis of the presence of schizoid traits. One of the splits in the British Psychoanalytic Society that Melanie Klein provoked was that she would use the term schizophrenia in such a loose way that medically qualified analysts, notably Edward Glover, wanted nothing to do with her. He reportedly said to Hannah Segal at her assessment for a training there that “In that case [Segal had begun her analysis with Klein] I have nothing to do with you! They’ve got their people; we’ve got our people. Goodbye” (<http://www.melanie-klein-trust.org.uk/segalinterview2001.htm>).

German psychiatrists used the term “schizoid” to include sensitivity, “introversion” (the term coined by the follower of Freud, CG Jung), and emotional detachment (Kretschmer), although there were many differences in detail and these are now reflected in the confusing DSM-IV descriptions of schizoid and schizotypal personality. They attributed it to temperament that was an expression of the broad phenotype of a genetic disposition to schizophrenia. This link has never been adequately established, however, and in clinical practice, depression seems to be a more commonly linked mental illness. Analysts attributed

schizoid personality to a disorder of object relations, and the research evidence points to that being the case (Lenzenweger 2010) although it also suggests that there is a hereditary, temperamental component, too (Cohen et al. 2010).

The term “schizoid” would not be relevant if it were not for the persisting notion that Asperger syndrome and schizoid personality disorder in children are different descriptions of the same condition (Wolff 2000). I have argued that people with AS may be more at risk of developing schizoid traits but that the two are quite distinct: One is a developmental disorder of brain development; the other is an emotional disorder, a disorder of mental development (Tantam 1988). However, the analytic stance on schizoidia may have reinforced the notion that autism, too, was psychogenic.

Getting information about outcome is particularly difficult for clinicians and researchers who see children or adults once or only at one stage of their development. This is commonly the situation for psychotherapists, including psychoanalysts. It is an even greater problem when their observations are confined to a few, albeit intensively studied, individuals – again a problem for psychoanalytic theorists.

Psychogenic Theories of ASD

Freud’s original formulation of an inner, autochthonous sexual drive continues to find some support as an explanation of deviant sexuality, but it was otherwise quickly replaced by post-Freudian accounts, except in the work of the influential French psychoanalyst, Jacques Lacan, who combined it with a semiological theory. He argued that drive had to be coupled to signification, in order to fill the “lack,” *béance*, that unsatisfied drive created. The final stage of signification, when drives emerge into our conscious awareness and we can find conscious ways of satisfying them, is its linkage to language and the symbolic order or “*le nom du père*.” Autism, as Lacan thought, occurs because this does not happen. He is credited as saying that the child with autism is too taken up with talking to himself that he cannot talk to others and also that when a child with autism hears his speech, it sounds like a hallucination, and he covers his ears to protect himself

from it (Tendlarz). It is tempting to think that Lacan may have been aware of Sir Michael Rutter’s briefly held view that autism was a language disorder. The linkage of desire to language is, in Lacanian terms, the “fourth stage of the cycle of the drive” that is the stage when, according to the solipsistic Freudian theories of infant development, the infant discovers the reality of other people (Lacan 1977). Some Lacanians attribute autism to a failure at the third cycle of the drive, leading to a developmental arrest at the stage before other people are recognized (Laznik 1993).

Developmental arrest is a very common psychoanalytic theme. Psychoanalysts suggest that development stops either because it “is fixated” because desire is too fully gratified (Freud postulated a series of sexually gratifying nursery nurses unknowingly fixating precociously prurient little boys) or because it is thrown back or regressed to an earlier stage by a disappointment, of which the type is the “Oedipal situation.”

In the 1920s, Freud began to consider that there was also a death instinct or rather an instinct to kill, as well as a sexual instinct, which he broadened into an affiliative or cooperative instinct. In his answer to Einstein’s question, “Why war?,” Freud thought that this destructive instinct might be overcome by an increase in the positive instincts as actions, Freud now thought, were motivated by the balance between these often opposing instincts. Kurt Lewin, who worked at the Institute of Social Relations in Frankfurt before moving to the USA, would have been familiar with these ideas, as the “Frankfurt school” was strongly influenced by psychoanalysis, and his formulation of the “approach-avoidance conflict” demonstrates this. For a short while, ASD was attributed to an irresolvable approach-avoidance conflict.

Freud’s idea of the protective effect of social solidarity did not apply to the Austria from which he fled in 1938 or any of the other Fascist powers which seem to have experienced an increase in in-group social harmony in proportion to their out-group violence. It may not be unrelated to this that the differences of children with autism from neurotypical children were first noted by both Asperger and Kanner in 1938, although

their observations were not widely published until just before the end of the war when some of the terrible civilian consequences of the war were becoming all too apparent.

The casualties of war included children orphaned, women bereft, men broken in the stress of battle, and people of all ages dehumanized. Psychoanalysts were involved in dealing with these crises. Fairbairn, who had described schizoid personality, worked with men who went absent without leave, for example. These war experiences changed the thinking of many health professionals dealing with children, and several of them saw a similarity between children with ASD and children who were traumatized in the war. Bruno Bettelheim, for example, who claimed to have been psychoanalyzed in Vienna and used Freudian concepts in his work, likened children with ASD to prisoners in a concentration camp and wrote that the mothers of these children were like the SS guards (Bettelheim 1967). His work did much to fuel the stigmatization of parents by professionals, particularly those that were psychoanalytically orientated, and in the end brought psychoanalytic approaches into disrepute, particularly after Bettelheim committed suicide and some of his ex-patients accused him of physical abuse of them.

Stress-Diathesis

Fairbairn's approach to men who went AWOL was that the stress of war brought out a latent overdependence on the mother and led to incapacitating separation anxiety. This is an example of what two other analysts called the "stress-diathesis" model (Grinker and Spiegel 1945): that a hidden vulnerability acquired in early development could lead to disorder if disclosed by a later stress. Over subsequent years, the most commonly postulated diatheses have been neurological and not, as originally proposed, psychological but the notion that stress can disclose ASD – an originally psychoanalytic concept – is still being propounded (Pfaff et al. 2011).

Few people would now discount Adolf Meyer's idea that circumstances, environment, and brain interact. So the stress-diathesis seems completely in harmony with this holistic

approach. But psychoanalysts are often normative thinkers, and any deviation from statistical normality has often been considered to be a diathesis that could lead to disorder. The evidence from neuroscience or genetics does not support this. Diversity in the brain and in the genes has survival value for the group because it allows for rapid evolution and for role differentiation within the group that confers adaptability.

Maternal Deprivation and Affective Contact

Curiously, the same 1948 issue of the *Journal of Mental Science* that contained a review of *Men Under Stress* (Issue 94) also contains review of a book on the psychology of the unwanted children by Agatha M. Bowley.

The war substantially increased the number of children without families: unwanted children, orphaned children, displaced children, evacuated children, all of them were more vulnerable to distress. In 1949, the World Health Organization, recognizing this, commissioned a psychoanalyst and director of the child psychotherapy training program at the Tavistock Clinic in London to report on these children. He concluded that there was a characteristic psychological reaction to what came to be called "maternal deprivation." The idea received powerful support from the cruel experiments of Harry Harlow who raised rhesus infants in isolation providing them with a series of inanimate mother surrogates. The maternal deprivation hypothesis was effectively laid to rest by Rutter (1981) but by this time had already been succeeded by Bowlby's much more nuanced attachment theory, developed in conjunction with Mary Ainsworth, among others. Attachment theory was partly inspired by *King Solomon's Ring*, a book of essays by the naturalist Konrad Lorenz (later joint recipient with Nico Tinbergen of a Nobel Prize for his part in creating ethology). Lorenz was brought up in a remarkable family who seem to have kept a menagerie in their Vienna flat. He was adopted by a family of goslings after their mother had died and postulated that an infant gosling imprinted on the first animal that they saw moving after they had hatched. Bowlby thought that this was an example of a more general process of "bonding" for which

there was intrinsic disposition – now thought to involve oxytocin and perhaps vasopressin surges in the mother – leading to grooming of the infant and a disposition to respond to a species-specific cry in the infant. Grooming by the mother changes the infant’s amygdala so that the infant treats the mother as a unique source of comfort from anxiety or threat and draws near to her protection under these conditions. Oxytocin probably mediates the proverbial savagery of a mother’s aggression when protecting her young, too. Bonding and oxytocin remain active areas of research in ASD.

Bowlby’s work was anticipated by Kanner. Kanner (1943) reported on 11 children, the first of whom, Donald, he saw in 1938. Many of these children would now be diagnosed as having Asperger syndrome.

Kanner’s descriptions are uncannily good. He noted that the 11 children had previously been diagnosed as having intellectual disability or schizophrenia but, as Kolvin later confirmed (Kolvin 1971), that schizophrenia could not apply as there was no period of normal development (although early development is still an important differentiator of ASD and schizophrenia, a period of early development is no longer considered unusual in ASD).

Kanner considered that the children that he was describing had a condition not previously described (he did not know of Asperger’s work), and he wrote that it was an “autistic disturbance of affective contact.”

Affective contact corresponds to Lorenz’ imprinting, and Bowlby’s attachment, but unlike Freud’s ideas of a sexual instinct which created a bond only when it had been shifted by learned experience from being directed to the self to being directed toward the mother, affective contact was purely biological. Kanner wrote that “... these children have come into the world with innate inability to form the usual, biologically provided affective contact with people.”

It is not clear why Kanner chose the words affective contact. They had been used in the 1920s in relation to schizophrenia <http://bjp.rcpsych.org/cgi/reprint/75/310/526-b> but also in relation to religious experience <http://www.jstor.org/pss/3745867>. (Flower 1929), but I could not

find any other reference to their use except, possibly, by the psychoanalyst and originator of the sandbox technique of play therapy, Margaret Lowenfeld, who began her career as a research scientist studying mother’s milk before becoming a child psychotherapist.

Blaming the Mother

Psychoanalytic approaches to autism have included one or more of five assumptions (see Textbox).

Textbox

Psychoanalytic assumptions leading to a psychogenic theory of ASD

That autism is a normal developmental stage

That autistic disorder is either an arrest or a regression to an earlier developmental stage as a result of some kind of stress, shock, or trauma

That the child has a diathesis to arrest or regression in the face of this stress, shock, or trauma that is psychological

That the stress, shock, or trauma most likely to be involved is separation from the mother

That rejection by the mother without physical separation may be enough stress, shock, or trauma to cause autism

Kanner’s 1943 description gave credence to assumption 5 (see Textbox), by his choice of the term “autistic” in the first place and by suggesting that emotional deprivation played a part in the “autistic disturbance”: “One other fact stands out prominently,” Kanner writes “In the whole group, there are very few really warmhearted fathers and mothers.... The question arises whether or to what extent this fact has contributed to the condition of the children.” Kanner strengthened his view that ASD could be psychogenic in a later paper (Kanner 1949) in which he first used the term “refrigerator parent” and gave credence to both elements 2 and 5 (Textbox) in his thinking. He wrote of children with ASD that “Their withdrawal seems to be an act of turning away from such a situation to seek comfort in solitude,” the situation being that “They were the objects of observation and experiment and not of genuine warmth and enjoyment.” Kanner thus gave his authority to a psychogenic account of the etiology

of autism and opened the way for the extremes of those like Bettelheim (1967) who would accuse the parents of children with ASD of being unfit, remove their children from them, and then, sometimes – or so some of those children have alleged – treat those children abusively. Bettelheim was not an analyst but was strongly influenced by Freudian theory.

Kanner's formulation of the children regressing in the face of some kind of trauma was entirely consistent with psychoanalytic theories of ASD at the time and indeed up to the 1980s. Frances Tustin's work was particularly influential in the UK and Lacan in France. Tustin had trained in a program directed by John Bowlby but remained resolutely Kleinian in her outlook, and she included all of the five elements mentioned in her early theories. She thought that the infant had to deal with both the life and the death instincts toward the mother. This was consistent with the object relations school of psychoanalysis, championed in the UK by Melanie Klein in opposition to more traditional approaches championed by Freud's youngest daughter, Anna. Klein's analysis of "Dick" described in *The Psychoanalysis of Children* (1932). In *The Writings of Melanie Klein*, Vol. 2. London: Hogarth Press 1975 is often taken as the starting point for psychoanalytic approaches to the treatment of ASD. Klein had previously analyzed her younger son, Erich, and was just completing her own analysis with Abraham. "Dick" was suffering from a psychological disorder that had been diagnosed as schizophrenia, but Klein considered that his mother had rejected him from birth and that as a result his "...symbolism had not developed. This was partly because of the lack of any affective relation to the things around him, to which he was almost entirely indifferent" (Klein 1975, pp. 223–224). Klein felt that this incapacity to symbolize was related to the abnormality of his "object relations," and what appeared to be a failure to understand people as people, toward whom he could show "opposition and obedience" or be "intelligible" (Klein 1975). She interpreted this impairment as being a result of "anxieties rooted in the child's relations with others..." and as "a manifestation of defenses

against his own destructive impulses toward the mother's body" (Morra 2002, p. 287).

Tustin's original formulation (in *Autism and Childhood Psychosis*) was that birth and bodily separation from the mother could lead to such negativity toward the mother that development was arrested at the "autistic" stage. Later, she detected "encapsulated autism" in children with many other conditions (*Autism and Childhood*). Toward the end of her career, she thought that autism was not a normal stage of development, a conclusion that another psychoanalyst who treated children with an ASD, Margaret Mahler, had come to much earlier. Mahler, unlike Tustin, had also concluded that children with an ASD had a biologically based disorder of affective contact and routinely included the mother along with the child in her analyses.

War Brings People Together

The impact of the Second World War was not confined to a front line of fighting men. Rapidly advancing armor and airplanes could spread it much more widely. As I noted earlier, many professionals were familiar with the civilian trauma that was a consequence of this. Children were often at much at risk as adults, and the image of the desolate and traumatized child has rarely been out of the newspapers, and out of our consciousness, since. The images of children traumatized by war have been joined by those of children beaten or neglected by carers, or institutionalized in Romanian, or Russian, orphanages. Psychoanalysts made important contributions to this awareness. Spitz wrote of institutionalism in children, and Bowlby of the consequences of "maternal deprivation." Maternal deprivation led, in Bowlby's view, to a lack of empathy and of emotional response that he called "affectionless psychopathy." He may have been influenced in this description by the interposition of a nanny or series of nannies between mother and child that was typical of an English upper class upbringing as well as by the wealth of research that he had reviewed for his WHO monograph (later published as Bowlby, J. (1951). *Maternal care and mental health* (p. 89). New York: Schocken).

The basic assumption in psychoanalysis that developmental disorders, like psychoses, were mental and not biological led many of its practitioners to reject Bowlby's idea that maternal deprivation affected the brain directly. They preferred Klein's idea that the child imagined what to expect of a carer and felt hostility toward a carer who did not come up to these expectations. Bowlby was ostracized in the British Psychoanalytic Society following three seminars that he had on attachment to the society, although he was rehabilitated after his appointment as Freud Professor of Psychotherapy at University College, London, in 1980. Since then, attachment theory has become mainstream.

Psychoanalysts and other psychotherapists often assumed that maternal deprivation could cause ASD. There were superficial similarities between children with an attachment disorder and children with an ASD although follow-up studies of neglected and traumatized children often withdrew from social interaction. They rocked, mumbled unintelligibly, masturbated or self-stimulated (echoes of autoeroticism), and related to objects but not to people. Follow-up studies of neglected children from Romanian and Russian orphanages provide strong evidence against these children with "attachment disorders" having the same course as children with an ASD, and therefore against the two conditions having a shared etiology. However, these findings could only have been made after a substantial number of children from Romania and Russian being adopted in Western Europe and North America, thus providing a natural experiment of the effects of early neglect. This only happened recently. So psychoanalysts could and, as we have seen, did fall into the same fallacy as Freud himself in thinking that similar symptoms meant a common cause.

Given the assumptions that the effects of maternal deprivation were purely psychological, and that maternal deprivation could cause ASD, it was not surprising that many psychoanalysts took the view that a child with ASD had been made that way by their parents. It was not the parents' objection to being so stigmatized that changed this, but

psychoanalysts' acceptance that Bowlby had been right, if not about maternal deprivation but about its successor, attachment theory. Most psychoanalysts now accept that there is a biological basis to ASD although continuing to believe – as indeed do most practitioners – that there are familial influences that might affect its expression. Some try to bolt on Kleinian concepts almost in their entirety to this biology, however, as if reluctant to yield the possibility that autism is really a mental disorder.

Recent Developments in Psychoanalysis

Bowlby's rehabilitation and the incorporation of attachment theory into mainstream psychoanalysis have been followed, either coincidentally or synchronously, by a reversed trend from the previous years. Scientific theories about ASD have been adopted into psychoanalysis, rather than psychoanalytic theories being applied to autism. Psychoanalysts are now taking developments from research in ASD and applying them to their own theories of mental functioning, applying these to neurotypical as well as people with ASD.

"Theory of mind" has been particularly susceptible since it is already a cognitive rather than a brain-based theory. Theory of mind sounds almost like "mindfulness," and in the way that thinking in this area seems to proceed, the two have been subsumed into a new kind of psychoanalytic approach that is targeted at a political priority, so-called borderline personality disorder (Fonagy and Bateman 2006).

Neuroscientists have also suggested that the mirror neuron theory of contagious emotion might also be applicable in psychoanalysis (Scalzone 2005), but this brain-based theory has met with much less response.

Future Directions

Alexithymia

Alexithymia was first posited by two Bostonian psychotherapists, Sifneos and Nemiah. They were struck that some people with psychosomatic disorders who got worse with psychoanalytic

treatment, rather than better. They attributed this to the inability of these people to put their emotions into words, that is, a lack of words for feelings, or alexithymia (Sifneos 1972). Frith suggested that alexithymia might also affect people with Asperger syndrome (Frith 2004). Like impaired theory of mind in anorexia nervosa, there is evidence that alexithymia might be particularly likely to occur as a result of disorder (Tantam et al. 1982) rather than as a cause of disorder. So, although it is important for psychotherapists to bear in mind that people with an ASD may be uncomfortable dealing with emotion words, it should not be assumed that this discomfort has led to their ASD but may be a consequence of a lack of previous narrative with other people about emotions. Psychoanalytic treatment relies heavily on analyst and participating in a discourse with the analyst about the emotional connotations of the words that they use. Alexithymia blocks this, meaning that analytic interpretations based on these connotations may be experienced by the analyst and as mysterious and threatening. The negative effects of psychoanalytic treatment of adults with an ASD, like psychoanalysis of people with schizophrenia, may be a consequence of this. Other person-centered or existentially orientated methods are more successful since they emphasize practical solutions.

Intersubjectivity

Relational psychoanalysis has emerged as an influential approach (Stolorow et al. 2002), especially in the USA. Its proponents sometimes locate its origins in the work of Guntrip and his two analysts, Winnicott and Fairbairn, already mentioned as the first psychoanalyst to use “schizoid” in psychoanalysis. Other influences are Laing, himself influenced by the Scottish school begun by Fairbairn (Sutherland 1989), and also Kohut. Existential analysis (van Deurzen 2002) was a strong influence on Laing and through him, on relational psychoanalysis, too.

A key concept for relational psychoanalyst is “intersubjectivity,” a term coined by Husserl (1973, originally published 1905). Stolorow,

Atwood, and Orange define this “. . . a field theory or systems theory in that it seeks to comprehend psychological phenomena not as products of isolated intrapsychic mechanisms but as forming at the interface of reciprocally interacting worlds of experience.”

Intersubjectivity as used by Husserl was purely mental, but it has been taken up by developmental psychologists who use it to describe the shared world of mother and infant (Trevvarthen and Aitken 2001) that they argue is based on interacting biological systems. In a recent book, I have described these interactions as evidence of an “interbrain” network, mediated by nonverbal communication (Tantam 2009). Trevvarthen and Aitken trace intersubjectivity as a development concept to work on interactional synchrony in the early 1970s. Daniel Stern, a psychoanalyst, was one of these researchers (Stern 1971) and is often considered to be one of the originators of relational psychoanalysis (Stern 1985). Like Sullivan (1953) and Foulkes and Anthony (1957), he rejected the conventional analytic view that the infant is born in a state of autistic self-preoccupation from which he or she needed to be awakened although he still took the view that a failure of “attunement” by the mother to the infant could lead to deviant development; he considered that the inability of the mother to attune to a child with autism was due to the child’s inability to make affective contact.

Autistic Psychopathy

“Lust” is a disturbing but gripping narrative of a woman who feels devoured by the sexuality and aggression of an alien species – men – who hold her in thrall. It is written by Elfriede Jelinek, a Nobel Laureate who had been referred to Hans Asperger as a child (Delantaye 2005), is also reputed to have been a patient of Hans Asperger. It is, perhaps, the life experience of someone with Asperger syndrome. The focus of this entry has, so far, been on the Kanner and his description of early childhood autism. However, Hans Asperger had almost simultaneously with Kanner published (Asperger 1944) his habilitation on children that

he described as having “autistic personality disorder” and that he had first reported in 1938 (Asperger 1938).

Although Asperger worked in the cradle of psychoanalysis, Vienna, he does not seem to have been influenced by the approach. He was sure that the condition that he described was a disorder of the brain (Hippler and Klicpera 2005) that could be partly or wholly circumvented by education. He wrote (2005) of children with Asperger syndrome learning rules of etiquette in the same way that they learned sums and of conflict-ridden intellectual training leading to assimilation to the community.

What is notable about Asperger’s work is the focus on peer relationships, rather than parenting relationships; his notion that the symptoms of children with ASD are an attempt to overcome their difficulties, and not a kind of pathology and that children with an ASD are not merely helpless victims: In fact, he wrote that they can sometimes be malicious. Psychoanalysis with its emphasis on pathology rather than resilience, on parents rather than peers, and on unconscious motives rather than effort and training is poles apart from this kind of thinking.

These children can take note of “rules of etiquette” given to them in a down-to-earth kind of way, which they then can fulfill – like they would a sum. The more “objective” such a law is – maybe in a form of schedule, which includes all possible variations of daily routines and which must be stuck to by both parties in the most pedantic kind of way – the better it will be. So it is not through a habit, which unconsciously and instinctively grows by itself but through conscious, intellectual training, in years of difficult and conflict-ridden work, that one will achieve the best possible assimilation to the community, which will be more and more successful with growing intellectual maturity.

Conclusion

For all the fascination of psychoanalysis, it has perhaps created too much of a focus on parent-

child relationships in the study of people with ASD and detracted from peer relationships. It has also led us to think too often of the symptoms of ASD as symptoms and to obscure the possibility that the actions of people with ASD are the expression of a uniqueness and resilience in the face of a different brain and therefore a different participation in the connectedness of society.

It is regrettable that psychoanalysis also contributed to a victimization of parents, especially mothers, that increased the burden on already heavily burdened families. On the plus side, psychoanalysis has focused on the development of thought and language in children with ASD that might still lead to a better understanding of the subjective experience of having an ASD. That it has not yet done so may be because, as Bowlby pointed out many years ago, psychoanalysis has prioritized the child’s imagination of threat at the expense of real danger and loss. Most of us do assimilate our life experience to an emotionally charged narrative about who and what has made us the way we are, and this is the stuff of psychoanalysis, at least new paradigm psychoanalysis (Rudnytsky 2008). People with an ASD lack the narrative facility of many neurotypicals (Losh and Capps 2003) and do not usually dip into and out of autobiographical memory. On the other hand, people with ASD, even those who are gifted, often experience victimization, exclusion, and loneliness that are all too based in reality and that are not just in the past but continue in the present (Wainscot et al. 2008). These experiences, along with the sometimes condemnatory attitudes that people with ASD may develop about neurotypicals, are often a more productive focus for psychotherapy than the presumed parental failure.

PEP-3

Description

The Psychoeducational Profile: TEACCH Individualized Psychoeducational Assessment for Children with Autism Spectrum Disorders – Third Edition (PEP-3; Schopler et al. 2005) is the most current version of an assessment developed by professionals at TEACCH to evaluate the skills and behaviors of 2- to 7- year-old children with suspected autism spectrum disorders. Similar to its predecessors, the PEP-3 was designed to (a) measure developmental strengths, weaknesses, and learning style to inform educational programming; (b) assist in the autism diagnostic process by obtaining information from caregivers and by providing opportunities to observe social, communication, and play behaviors; and (c) provide developmental ages and other scores for diagnostic decision-making, educational planning, and/or assessing change in behavior and development over time. As such, the PEP-3 has utility in clinical, educational, and research contexts.

Developmental subtests on the PEP-3 assess early cognitive abilities, language/communication, and motor skills. Subtests included are cognitive verbal/preverbal, expressive language, and receptive language, which together comprise the communication composite, and fine motor, gross

motor, and visual-motor imitation, which together comprise the motor composite. Each developmental subtest item is scored as passing (the child can execute the task successfully without needing a demonstration), emerging (the child demonstrates some knowledge of how to complete the task but needs demonstration or practice), or failing (the child does not attempt or is unable to complete any aspect of the task). Raw scores are converted to developmental ages, percentiles, and developmental levels.

Maladaptive behavior subtests on the PEP-3 assess behavior areas related to an autism spectrum diagnosis. Subtests included are affective expression, social reciprocity, characteristic motor behaviors, and characteristic verbal behaviors, which together comprise the maladaptive behavior composite. Ratings for the maladaptive behavior subtests are based on observations throughout the assessment, and each item is scored as appropriate (the behavior is appropriate for the child's chronological and overall mental age), mild (the behavior is slightly or mildly unusual for the child's chronological and overall mental age), and severe (the behavior is unequivocally unusual or dysfunctional). Raw scores are converted to percentiles and adaptive levels. New PEP-3 software can be used to assist with scoring, statistical analyses, graphing, charting, and report generation.

The caregiver report component is a questionnaire completed by a caregiver, such as a parent, guardian, or teacher, based on his or her daily observations of the child. Two sections ask caregivers to provide estimates of the child's developmental level in several areas and rate the applicability and severity of several diagnostic labels. This information provides the examiner with a broader perspective of the child's overall strengths and weaknesses and helps the examiner understand the caregiver's perceptions of the child. The caregiver report also has subtests asking caregivers to rate behavioral problems associated with autism, skills in personal self-care, and adaptability and responses to the environment. Caregiver ratings are scored as appropriate, mild,

or severe, and raw scores are converted to percentiles and developmental/adaptive levels. A developmental age equivalent can also be computed for personal self-care skills.

The item content and administration procedures of the PEP-3 were designed to maximize its utility in children with autism spectrum disorders. Test materials are manipulative and interesting to young children, and with the exception of the language subtests, items require minimal language ability. Items are not timed, and tasks can be administered in an alternative order if doing so will make the assessment more engaging or appealing for the child. Further, given the scattered skills often shown by children with autism spectrum disorders, basals and ceilings are not used, though examiners may credit lower level skills when higher level skills are demonstrated. Finally, performance on test items readily translates into educational planning goals, and observation of the child during the assessment provides information about his or her learning style and the best way to begin teaching those goals.

Historical Background

The development of the PEP-3 (and its two earlier versions) (Schopler and Reichler 1979; Schopler et al. 1990, 2005) parallels the understanding, assessment, and treatment of autism from the 1940s through the present. The early formulations of autism were based on psychogenic principles attributing the atypical behaviors to profound emotional disturbances caused by faulty parenting. The apparent intellectual deficits shown by the majority of cases were considered pseudo-mental retardation, a mask covering up normal intelligence. The “islets of intelligence” noted by Kanner were offered as evidence of normal abilities. The children who were tested failed to score anywhere near the normal range and also were difficult to manage in the assessment setting. The concept of “untestable” was used to describe these children. It was in this context that Schopler and Reichler, in their pioneering research in autism in the 1960s and early 1970s, determined

that an appropriate assessment instrument, developmentally-based and geared to the unique characteristics of children with autism, would demonstrate that not only could these children be fairly tested but also meaningful individualized information could be gathered to help with diagnosis and program planning.

At that time, the main tests used were the Stanford-Binet and Wechsler Scales, designed for language-proficient children with relatively even patterns of skills and adequate competence, motivation, and relating. Only the brightest of children with autism could be expected to successfully take these tests, and, even then, their responses and scattered skill profiles might be misinterpreted. The introduction of the PEP, an autism-specific assessment tool, addressed the long-standing problems inherent in testing based on the misunderstanding of the children. By using an instrument based on developmental principles and administrative flexibility, examiners not only were able to obtain accurate information, but the understanding of the nature of autism and how it affected children was better appreciated.

Another insight Drs. Schopler and Reichler highlighted was the distinction between diagnosis and individualized assessment, particularly relevant to autism. Diagnosis involves the grouping of cases based on a set of common characteristics, while individualized assessment pertains to the specific profile of skills, deficits, interests, and behaviors. In their research, Schopler and Reichler developed both the Childhood Autism Rating Scale (originally the Childhood Psychosis Rating Scale) and the PEP as companion scales, with the former addressing diagnosis and the latter individualized assessment, with both emphasizing direct observation. The PEP was also unique in its integration of behavioral and developmental data in one instrument, emphasizing the importance of linking the atypical features with the developmental delays and irregularities. Autism was meant to be understood as a disorder of development, not an emotional or primarily behavioral disturbance, and the PEP was a means of documenting this.

The first published edition of the PEP was in 1979, although a working version had been available within the TEACCH program during that

decade. The first revision, the PEP-R, was published in 1990 in response to the increased numbers of younger children being diagnosed with autism and the passage of PL 99-457 expanding public school services for exceptional children under the age of five. The revised PEP added many items developmentally at the three and under age range. Other changes included expanding the language functioning area, streamlining sections dealing with the assessment of behavior problems, and modifying terminology to meet current definitions and usage. The second revision, the Psychoeducational Profile – Third Edition (PEP-3) was published in 2004. In addition to improving psychometric properties (e.g., larger normative sample, more reliability and validity data), the PEP-3 also updated behavioral items to be more consistent with current research on characteristics of autism and added a caregiver form to gather information on self-care skills, autism characteristics, and adaptive behavior.

Psychometric Data

The PEP-3 was developed using a normative sample comprised of 407 children and adolescents with ASDs and 148 children with typical development from around the United States. Development data were collected by professionals who had experience with the PEP-R and/or work as psychologists within the TEACCH program. Overall, analysis of reliability and validity indicates that the PEP-3 demonstrates sound psychometric properties (Schopler et al. 2005).

The PEP-3 demonstrates high reliability (Schopler et al. 2005). Internal consistency was assessed by calculating coefficient alphas for all subtests and composites in a sample of individuals with ASDs at 11 age intervals (ages 2 through 12). Average coefficients indicated high reliability and for the developmental subtests ranged from 0.92 to 0.97, for the maladaptive behavior subtests ranged from 0.90 to 0.93, and for the caregiver report subtests ranged from 0.84 to 0.90. Test-retest reliability was assessed over a period of 2 weeks in a sample of 33 children with ASDs. Raw scores were used to calculate correlation

coefficients for each subtest, and all indicate high reliability: developmental subtest correlation coefficients ranged from 0.97 to 0.99, maladaptive behavior subtest correlation coefficients ranged from 0.94 to 0.98, and caregiver report subtest correlation coefficients ranged from 0.98 to 0.99. Interrater reliability for the caregiver report subtests was assessed for 31 children with ASDs and 9 children with typical development. Two parents for each child completed the caregiver report form. Polychoric correlation coefficients were calculated for each item due to the ordered, categorical nature of the data. Coefficients ranged from 0.70 to 0.91 for the problem behaviors subtest, from 0.65 to 1.00 for the personal self-care subtest, and from 0.52 to 0.90 for the adaptive behavior subtest. One additional item on the adaptive behavior subtest was excluded from the calculation ranges due to its low reliability.

Criterion-prediction validity was assessed in a series of studies correlating scores from the PEP-3 with scores from other developmental and behavioral assessments used to measure similar constructs. Overall, the vast majority of correlations were large (0.50 and above) and in the expected direction, thus supporting the validity of the PEP-3 as a measure of development and autism characteristics (Schopler et al. 2005). In the first study, correlations between the PEP-3 subtests and subtests from the Vineland Adaptive Behavior Scales (VABS) were computed for a sample of 45 children and adolescents with ASDs. The VABS is a parent report measure of child adaptive behavior and self-care skills. As expected, positive and significant correlations were found between the VABS and the PEP-3 for subtests related to developmental skills, self-care skills, and behaviors related to an autism spectrum diagnosis. Lower correlations were found between PEP-3 caregiver report of problem behaviors and VABS scores of motor and daily living skills, though these scales were not predicted to correlate highly. In the second study, correlations between the PEP-3 subtests and total scores from the Childhood Autism Rating Scales, a measure of autism symptom severity, were computed for a sample of 68 children and adolescents with

ASDs. Because higher scores on the PEP-3 reflect a more typical pattern of behavior and higher scores on the CARS reflect a more impaired or autistic pattern of behavior, significant negative correlations were predicted and found. Similarly, the third study examining the relation between the PEP-3 and the total score on the Autism Behavior Checklist – Second Edition in 316 individuals with ASDs yielded significant negative correlations between the measures except for the PEP-3 characteristic verbal behavior subtest.

The PEP-R and the PEP-3 have been translated into several languages including Chinese, Japanese, French, Portuguese, Dutch, Italian, and Estonian. Although some versions may benefit from further study, evidence available in English indicates that translated versions continue to show strong reliability and validity, and the PEP is a valuable instrument internationally for assessing children with autism (De Leon 2005; Fu et al. 2010, 2011; Kikas and Häidkind 2003; Steerneman et al. 1997; Villa et al. 2010).

Clinical Uses

The PEP-3 has multiple clinical and educational purposes including gathering developmental data for program planning and informing diagnostic decision-making, although it should not be used as a stand-alone measure for making a diagnosis. However, the PEP-3 collects information on the behavioral characteristics associated with ASD. It has normative data based on a large sample of children with autism, particularly useful in clarifying the extent to which the child being tested shows features shared by the sample of children with ASD. The PEP-3 can be used as the primary test in the evaluation process, but it should be supported by other information such as parent report, observations in a natural setting (e.g., home or school), previous history, and collateral reports. When diagnostic clarification is a primary goal of the evaluation, it is preferable if the PEP-3 is used in conjunction with the Childhood Autism Rating Scale, the Autism Diagnostic Observation Schedule, or another scale specifically designed for diagnostic classification.

Perhaps the greatest utility of the PEP-3 is in generating developmental information across multiple function areas. A strength of the test is that it was designed specifically for children with autism; it can be flexibly administered, contains materials of interest to children, and does not depend on language for instructions. The nonverbal domains and items do not require language processing for the child to complete them. The test covers a wide range of important developmental functions. Examples of test flexibility include the options of alternating easy and challenging activities, conducting the assessment using work systems or routines familiar to the student, and teaching and scaffolding to get complete information.

Developmental age scores can be derived and can be converted into a developmental quotient (Delmolino 2006). However, more important to program planning is the breakdown of skills into patterns as well as item analysis. In reviewing the data, the clinician is able to consider multiple levels of analysis including examining the child's overall pattern of strengths and weaknesses, analyzing the individual items that were passed or where an "emerging" score was obtained, reviewing the pattern of maladaptive behaviors, and considering the caregiver information. A careful analysis provides insight about appropriate developmental expectations useful in planning goals and curriculum.

Each of the developmental functions or domains is made up of many items that tap a variety of skills. For example, the Cognitive Verbal/Preverbal Scale measures the skills of problem-solving (nonverbal), matching, sorting and categorizing, and visual-motor integration. In addition, the examiner can observe characteristics of social communication (e.g., directing attention or commenting, seeking help or praise, sharing enjoyment), cognitive style (e.g., organization, flexibility, ability to transition between materials, persistence, cognitive areas of strength and weakness), and use of and response to materials (e.g., appropriate or inappropriate, unusual sensory responses, rigid or flexible). Results from performance on the different developmental domains can be used to develop instructional goals, curriculum, and behavioral strategies for

implementation at school and home. Integrating the information from the developmental and behavioral scales leads to a well-rounded approach to intervention and program planning. Other resources are available that show examples of how skills can be taught in a visual, structured way (Boswell et al. 2005; Eckenrode et al. 2003, 2009).

Intelligence tests (see specific tests); IQ test

Definition

Assessment is the process by which a professional meets with and evaluates an individual, family, or family subsystem for a determined need. There

are many different types of assessments. The presenting concerns of the individual, family members, or family system should determine the type, focus, and amount of testing. Most often, assessment is conducted with individuals. Depending on the age of the individual, in addition to a diagnostic evaluation, assessment of the domains of neurocognitive, academic, language, adaptive, and social-emotional functioning and behavior problems is routinely recommended for individuals who have been identified as having, or as at risk for an, autism spectrum disorder (ASD).

Assessment can be both formal and informal. However, all methods of assessment should be completed with the aim of gaining information about an individual that will aid in making informed decisions. There are many purposes of assessment: screening, problem solving, diagnosis, counseling and rehabilitation, and evaluating treatment progress. In some circumstances, it may be possible to complete one assessment that can inform several of these purposes. However, in other circumstances, multiple specialized assessments may be required to obtain the information necessary to develop an accurate picture of the individual and the most complementary treatment plan (Sattler 2001).

Screening assessments are brief evaluations designed to signal initial risk for a particular disorder, condition, or problem. Examples of autism screeners include the Screening Tool for Autism in Toddlers and Young Children (STAT; Stone and Ousley 2008) and the Social Communication Questionnaire, Revised (SCQ-R; Rutter et al. 2003a). These brief observation and questionnaire tools are generally quite sensitive, thus ensuring that children who are at risk get the additional assessment needed to determine or rule out an ASD diagnosis. Another highly sensitive screener of emotional and social functioning is the Infant Toddler Social Emotional Assessment (ITSEA) (Briggs-Gowan and Carter 2006). This screener may be a good first tool in assessing general social and emotional competence before deciding on using an autism specific screener.

A problem-solving assessment is a detailed evaluation of a specific concern, or area of functioning. These assessments are often used to

determine whether or not an individual has a specific diagnosis, such as an ASD. The Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2002) and the Autism Observation Scale for Infants (Bryson et al. 2007) are two examples of problem-solving assessments often used as part of an evaluation designed to diagnose ASDs.

A comprehensive psychological assessment requires a detailed evaluation of an individual's functioning in more than one area. This type of assessment often results in a profile of an individual's strengths and weaknesses in areas such as academics, cognition, language, and social functioning. These types of assessments allow for accurate diagnoses and treatment plans to be made that best aid the individual in achieving at their highest ability. One important addition to the comprehensive evaluation is intelligence testing. This is especially important for individuals with an ASD given that intellectual ability has been linked to severity of autism symptoms, ability to acquire skills, level of adaptive functioning, and overall trajectory (Ozonoff et al. 2005). Commonly used cognitive tests for individuals with an ASD include the Wechsler Intelligent Scale for Children, Fourth Edition (WISC-IV; Wechsler 2003), the Differential Ability Scales-II (DAS-II; Elliott 2007), the Mullen Scales of Early Learning (MSEL; Mullen 1995), and the Leiter-Revised (Leiter-R; Roid and Miller 1997). The Leiter-R is an especially useful tool for individuals with limited language. Additionally, language assessments are also imperative to assessments of individuals with an ASD. Expressive language level is the second best predictor of overall trajectory (Ozonoff et al. 2005). Common, relatively brief receptive and expressive vocabulary tests used with individuals with an ASD include the Peabody Picture Vocabulary Test (PPVT; Dunn and Dunn 1997) and the Expressive One Word Vocabulary Test (EOWPVT; Martin and Brownell 2000), respectively.

Counseling, rehabilitation, and adaptive assessments focus on the individual's abilities, rather than their weaknesses. These assessments evaluate the individual's abilities to adjust and successfully complete daily responsibilities. A common measure that may be used with

individuals with an ASD to assess adaptive behavior is the Vineland Adaptive Behavior Scales II (Vineland II; Sparrow et al. 2005). This Vineland-II is a semi-structured parent interview that assesses an individual's daily living skills. Additionally, the TEACCH Transition Assessment Profile (TTAP; Mesibov et al. 2007) could also be utilized as a direct assessment of an individual's ability to complete daily tasks such as answering the phone, counting money, and sorting. The TTAP also includes parent and teacher interviews as well.

Progress evaluation assessments occur periodically after initial assessments to track an individual's changes in development and to evaluate the effectiveness of treatment.

Historical Background

Modern psychological testing originated a little less than one hundred years ago with the development of some basic sensory and motor measures by British scholar, Francis Galton. Following Galton's initial development of testing, American psychologist, James McKeen Cattell continued this work throughout his academic career, revolutionizing testing, beginning with his paper "Mental Tests and Measurements," published in 1890.

Moving forward to 1943, Kanner offered the first description of autism when he identified a subset of individuals with intellectual disability. These individuals suffered deficits of social and communication skills that predominantly occurred in boys (Kanner 1943). Assessment of autism has long been left to the clinical interview with the aid of the Diagnostic and Statistical Manual of Mental Disorders (DSM). Autism was first mentioned in DSM-I under Schizophrenic reaction, childhood type (Author 1952). It was not until DSM-III, launched in 1980, that Autism was considered a unique diagnosis (Author 1980). While several diagnostic questionnaires and clinical interviews have been in use for many years, it was not until the ADOS was developed that clinicians were able to assess autism through the process of provoking behavioral

symptoms through presses during a semi-structured interaction (Lord, Rutter, and DiLavore 2001). The ability to assess autism symptoms from a behavioral observational perspective has provided assessors with a first-hand method of assessing and evaluating an individual's behaviors as opposed to relying on second-hand accounts in isolation.

Current Knowledge

While there have certainly been historical missteps in the application of psychological assessment throughout the evolution of the practice, including the damaging role of prejudicial psychological assessment in the Immigration Restriction Act of 1924, assessment remains a useful and critical tool of understanding one's unique individual profile (Gregory 2004). Today, there are clearly defined standards and general protocol to follow. Additionally, psychologists today should practice with the understanding that while general profiles can be created for different diagnoses, cultural influences are important and should be considered within each unique case.

An important distinction exists between psychological testing and psychological assessment. The emphasis on psychological testing is rooted in data collection, whereas psychological assessment is not purely focused on data collection through tests, but is concerned with a more global evaluation of an individual. Current theory dictates that there are four important "pillars" of psychological assessment.

The four pillars of assessment include norm-referenced tests, interviews, observations, and informal assessment procedures (or, more generally, tests). An assessment that incorporates each of the four pillars is considered to be a good representation of an individual's unique profile (Sattler 2001).

Norm-referenced tests are considered to be critical in conducting psychological assessments (Carter, Godoy, and Marakovitz 2009). These tests are standardized on a clearly defined group and are scaled so that each score indicates an individual's rank within the normed group.

Norm-referenced tests are most commonly used to assess intellectual ability, academic achievement, adaptive behavior, and fine/gross motor skills (Sattler 2001). Norm-referenced tests allow for quantification of an individual's behavior. Quantification can be helpful in determining where an individual ranks in comparison to his/her chronological peers, determining the location of specific deficits/strengths, and providing a baseline to track progress. It is important to select standardized tests that have a sufficient number of items at the level at which an individual is functioning so that there is sufficient variation in functioning to observe relative strengths and weaknesses, or sufficient sensitivity to develop a cognitive profile that is not subject to floor effects.

Norm-referenced rating scales are often used given that they are inexpensive and can be administered flexibly (i.e., online, through the mail, in person). Additionally, norm-referenced rating scales can be used to enrich a comprehensive assessment of an individual by asking teachers, employers, daycare providers, and others in an individual's daily life to complete questionnaires as well (Carter et al. 2009).

Interviews with multiple informants are another key component to a sound assessment. This is especially true for individuals with ASDs, as symptom severity may depend largely on the environment (Ozonoff et al. 2005). For example, high-functioning individuals with an ASD may appear to be astute and connected with their schoolwork and peers in a class that they both are interested in and excel in. However, that same individual may have severe difficulties maintaining a part-time job as a cashier due to the many social demands of the position and a lack of interest. Interviewing a child's parents, teachers, and other caregivers provides critical insight into the child's functioning in several different environments. Interviews can be structured, semi-structured, or unstructured. While all interviews provide the opportunity for information to be delivered in a conversational matter, structured interviews are the most rigid with a set list of questions and often result in a comprehensive caricature of the individual and are usually designed to aid in diagnosis. The Autism

Diagnostic Interview-Revised (ADI-R; LeCouteur et al. 2003) and the Childhood Autism Rating Scale, Second Edition (CARS2; Schopler et al. 2010) are popular semi-structured parent interviews used to contribute to a diagnosis of ASD. Both the ADI-R and the CARS 2 review, with parents, critical information regarding the affected individual's communication, social, and behavioral development. Assessment of these three domains is an important piece of a comprehensive assessment of an individual with an ASD (Ozonoff et al. 2005). Semi-structured and unstructured interviews provide less structure but are also important to the assessment of an individual because they give the opportunity for information to be transmitted that may have been lost in a more structured and formal setting. While structured and semi-structured interviews provide an in-depth amount of information they are more commonly utilized in research settings (Carter et al. 2009).

Observations are another critical component of psychological assessment. Observations can be made both formally, through observational assessment tools such as the ADOS (Lord, Rutter, and DiLavore 2001), and/or informally throughout the evaluation and/or in other environments (e.g., school, work, community). Observations are important because they allow a clinician to identify factors that may be contributing to, or reinforcing, specific problem behaviors. Through making these direct observations, clinicians are then better able to create effective, personalized, intervention plans.

Assessments of individuals with an ASD should also strive to be multidisciplinary whenever possible. Professionals from psychology, psychiatry, pediatrics, and neurology and speech and language specialists are often imperative members of the treatment team. While interdisciplinary coordination is essential to promoting quality care it is important that one professional take the lead as the evaluation coordinator. The evaluation coordinator should communicate with the parent and the affected child/adult in order to ensure that all information is equally shared and that the family only needs to speak with one professional who will then disseminate the

information. Utilizing an evaluation coordinator is essential to a successful evaluation and ensures accurate transmission of information (Ozonoff et al. 2005).

In regard to informal assessment procedures, or tests, there are many different options for clinicians to choose from. It is important to choose tests that assess for the information that is pertinent to the individual's needs. It is important to use tests that have sound reliability and validity. If a test does not have either of these qualities, it should be used cautiously (Sattler 2001). Additionally, measures of sensitivity and specificity are especially important psychometric issues to evaluate when considering which test to administer. High percentages of sensitivity and specificity ensure that a test is sensitive enough to capture enough of a population for screening purposes, but restrictive enough to not overwhelm service systems (Carter et al. 2009).

Although the four pillars of assessment do not operate independently, they are unique. Each pillar contributes to the overall assessment and creates a vivid picture of the individual's strengths, weaknesses, and overall level of functioning. A quality assessment should be derived from a number of sources, assessment methods, and cover multiple domains of functioning (e.g., intelligence, memory, oral language, adaptive behavior, etc.). Following completion of the assessment, results should be calculated, substantial evidence in the form of observations should contribute to sound clinical impressions, and recommendations should then be made to facilitate treatment (Sattler 2001).

When completing an evaluation it is especially important to interpret the scores by considering what they suggest about the individual's strengths and weaknesses. Clinicians should be careful to not interpret scores at face value as they diminish the qualitative data gathered in the assessment period and may overgeneralize an individual's profile. For example, an individual may have a low adaptive behavior score but may be capable of completing high-level tasks such as preparing a simple meal. If only a low score was interpreted from an adaptive behavior scales interview, a recommendation might be made to focus on self-help skills, such as preparing simple meals. However,

given that the individual has already mastered this skill, the recommendation is not useful in facilitating adaptive growth.

When assessing individuals for ASDs, two levels of screening and evaluation exist. Level 1 screening involves observation by routine service providers, such as pediatricians. Level 2 evaluations involve comprehensive diagnostic assessments provided by an experienced clinician (Ozonoff et al. 2005). Comprehensive diagnostic assessments should take into consideration the developmental component of ASD. Generally, children are diagnosed with ASDs in early childhood and continue to fit criteria through the life span.

When considering psychological assessment of young children at risk for a diagnosis of an ASD it is important to understand the challenges of assessing infants and toddlers. Often psychological assessments of young children focus on social-emotional problem behaviors, without equal focus placed on social-emotional competencies. While it is understandable that externalizing behaviors often drive parental concern and therefore prompt assessment, it is arguable that focusing on a child's competencies allows clinicians to gain more insight into the overall profile of the child. Namely, recognizing a delay in social and emotional competencies indicates risk for the emergence of additional behavior problems. Further, competencies in areas of social-emotional functioning generally indicate continued mastery. Knowledge of both social-emotional problems and competencies contribute to better treatment plans that capitalize on a child's strengths (Carter et al. 2009).

It is also important to take into consideration the contexts of race, ethnicity, and culture when completing an assessment. Often, race, ethnicity, and culture are used interchangeably as different ways of stating the same thing, when they are distinctly different constructs. Race, is a socially constructed concept that has been created based on physical characteristics. Culture is distinct in that it describes the shared values, beliefs, and practices of a group that are transmitted across generations. Lastly, ethnicity indicates a specific culture and is usually associated with a common geographic or national origin (Carter et al. 2004). Assessments that incorporate sensitive understanding of these

three domains contribute to a comprehensive understanding of the affected individual that takes into account factors other than test scores and addresses potential clinician biases.

Future Directions

While psychological assessment has certainly made advancements since the 1890s, both in developing the sophistication of the testing instruments and in considering cultural issues, assessment is not a perfect science. Certainly, the four pillars of assessment and integration of empirical knowledge of specific disorders and profiles contribute to a useful conceptualization of an individual's functioning. However, as assessment tools continue to develop, it is important to consider the imperfections that currently exist and work toward rectifying them in an effort to further advance the field. For example, it may be helpful to develop diagnostic specific norms for different measures of assessment. Developing norms that are specific to different diagnostic groups allows clinicians to make quantitative impairments within groups, thus allowing for more specific recommendations and expectation.

Psychomotor development

Definition

As typically used in psychology, psychomotor skills are those abilities that are related to motor activity in association with cognitive/mental activity. A number of psychomotor skills must be learned by the young infant including coordination, movement of the body, coordination of movement with thought/intention, and so forth. Complex psychomotor skills include activities like dancing, pitching, or playing a musical instrument.

Early investigators like Arnold Gesell (1949) charted the progress of early psychomotor skills and noted that, in general, there was a cephalocaudal ("head to tail") and proximodistal ("inner to outer") pattern of motor control, e.g., head control before trunk control and shoulder control before hand control. Other investigators like Piaget (1952) were more interested in the way that the development of thinking interrelated to motor control with coordination of early motor and perceptual abilities and simple reflexes into much more cognitively and motorically complex action. Some of the early work on charting the normative acquisition of skills also highlighted patterns of delay and developmental deviation. For example, delays in imitation skills in autism appear to reflect a fundamental lack of social orientation and interest rather than deficits in motor skills as such and may be important implications for treatment (Ingersoll et al. 2007; McDuffie et al. 2007).

involve some aspects of conceptual or psychological functioning. The term Psychomotor Developmental Index (PDI) is most closely associated with the Bayley Scales of Infant Development (BSID), first published by Nancy Bayley in 1969 and revised in 1993 as the BSID-II. The BSID-II includes the following three scales, mental, motor, and behavior, with the motor scale referred to as the Psychomotor Developmental Index (PDI). Test items for the PDI include motor skills such as rolling, crawling, grasp, and use of utensils.

Assessment of developmental functions emerged in the twentieth century with the advent of assessments such as the Gesell System of Developmental Diagnosis (1925), the Cattell Infant Intelligence Test (1940), and the original Bayley Scales of Infant Development (1969). These assessments focused on documenting normative expectations and were aimed at identifying a child's developmental progressions. Over time, these assessments also led to efforts to identify developmental delays for the purpose of planning appropriate early interventions.

Psychopathology

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

The study of developmental aspects mental illness is a term used in the field of mental health in a way equivalent to the use of the term pathology (illness) in other parts of medicine. The area of psychopathology is concerned with mental disorders and maladaptive/abnormal aspects of behavior or development. This area is one of concern to many different disciplines including psychiatry, psychology, and social work. Research work in the area ranges from the level of the brain and gene to the expression of maladaptive patterns of behavior/development in the individual and to cultural and epidemiological studies.

The most widely used guides to descriptive psychopathology are the DSM (*Diagnostic and Statistical Manual*) of the American Psychiatric Association and the ICD (International Classification of Diseases) manual; the former exists in one form for both researchers and clinicians and the latter in two different guides: one for researchers and another more general one for clinician. It is important to note that of itself difference does not imply psychopathology and that the cultural, family, and other factors may greatly impact the way mental disorders are expressed. Developmental factors are also particularly important for

disorders, like autism, which arise in the first years of life and may impact many aspects of subsequent development and functioning. Having one disorder may also increase the risk for others (what is termed “comorbidity”). In addition to the study of specific patterns of distress/impairment at the level of disorders, the term psychopathology can also be used to refer to specific symptoms or behaviors suggestive of mental illness, e.g., delusions or hallucinations.

Definition

This term refers to the combination of psychological and social factors as relevant to the development of the individual. The term was used by Erikson in his elaboration of life span model of development characterized by tensions typical of each age level. In some ways, research on psychosocial factors in autism was inhibited by the early focus on (and blaming of) parents and parental psychopathology in the etiology of autism (see Riddle 1987 for a review). As it became apparent that autism was a strongly brain-based and highly genetic disorder, work on psychosocial factors diminished substantially. It has increased in recent years with an awareness of the many and varied factors that can enhance (or inhibit) the optimal development of children with autism. This work has now included family factors including aspects of parenting (Rodrigue et al. 1992) and of sibling development (Rodrigue et al. 1992) as well as the importance of interventions in this area (Lord et al. 2005). The perspective of various relevant adults on the impact of psychosocial factors (Foley Nicpon et al. 2010) as well as the interaction of biological factors and psychosocial risk (Rutter and Casaer 1991) has also been explored.

Psychosocial Effects of Soft Skills Training for Young Adults with Autism

Connie Sung

Department of Counseling, Educational Psychology and Special Education, Michigan State University, East Lansing, MI, USA

Definition

Work-related social skills interventions designed and developed to help transition-age individuals (14–24 years old), including young adults with autism, improve their soft skills through a manualized curriculum delivered in school- or community-based settings. Soft skills, which are intra- and interpersonal qualities that are transferable across contexts (e.g., social-communication skills, positive attitude, responsibility, problem-solving, flexibility, time and stress management, networking, teamwork, work ethic, professionalism, etc.) are important for workplace success.

Historical Background

Autism spectrum disorder (ASD) is a lifelong neurodevelopmental disorder characterized by persistent impairments in social communication and interaction, repetitive patterns of behaviors, restrictive interests or activities, and sensory processing abnormalities (APA 2013). According to Centers for Disease Control and Prevention, there has been a dramatic rise in the prevalence of ASD over the past decade, with approximately 1 in 54 children diagnosed with ASD in the United States (Maenner et al. 2020). In addition to the rapid increase in prevalence, approximately 60,000 youth with ASD turn 18-years-old each year in the United States (Anderson et al. 2018; Roux et al. 2013), and close to half a million youth with ASD will enter adulthood and seek employment over the next decade (Roux et al. 2015).

Social, Vocational, and Psychological Challenges Faced by Young Adults with ASD

While individuals on the autism spectrum exhibit a broad range of functioning, symptom severity, and intelligence, impaired social communication and interaction are hallmarks of ASD, leading to difficulties understanding nonverbal and abstract verbal interactions with resultant problems in forming relationships and social networks, as well as obtaining and maintaining employment. While many young adults with ASD affirm interest in and possess the talent and capacity for long-term, competitive, and integrated employment, their characteristic challenges with social communication and adaptive functioning skills often significantly impact their ability to gain employment or live independently (Anderson et al. 2014; Seaman and Cannella-Malone 2016). Specifically, socially awkward behaviors, poor eye contact, sensory processing abnormalities, difficulty with perspective taking, literalism, repetitive behaviors, restricted interests, and difficulty reading social cues all have the potential to disrupt social interaction, particularly in workplace settings where awareness of ASD may be limited or misunderstood.

In addition to the social skills deficits inherent to the diagnosis, individuals with ASD experience

disproportionate levels of anxiety and depression. Vickerstaff et al. (2007) found that older age and higher IQ predicted lower self-perceived social competence and higher levels of anxiety and depressive symptoms among children with ASD. In fact, many individuals with ASD, especially those with normal intelligence (IQ), are cognizant of their social difficulties. Additionally, as children with ASD transition into adulthood, social demands become more complex and their social deficiencies become more noticeable as a result of the loss of structured social supports they are often provided during the school years (Hillier et al. 2011; White and Roberson-Nay 2009). Consequently, young adults with ASD may choose to socially withdraw rather than risk repeated social failure.

The social skills deficits (Howlin and Moss 2012) and mental health challenges (White and Roberson-Nay 2009) of young adults with ASD complicate their participation in transition activities. Due, in part, to these persistent struggles, their postsecondary education and employment outcomes have been very poor, creating a tremendous extended burden on their psychosocial well-being. Results from the National Longitudinal Transition Study ([NLTS-2]; Newman et al. 2011) indicate that young adults with ASD experience lower employment rates (37.2%) than any other disability category and markedly disparate employment rates when compared to their peers without disabilities (54%). Compounding the problem, those with ASD who manage to obtain employment are underemployed, typically receiving low pay and limited working hours (Taylor and Seltzer 2011; Roux et al. 2013). Furthermore, the majority of those with ASD are not participating in employment training or postsecondary education in the critical first 2 years after high school (Anderson et al. 2014; Shattuck et al. 2012). For example, a secondary analysis of the NLTS-2 data indicated that, among 680 youth with ASD, 28% had attended a 2-year college; 1% a 4-year college; 9.3% a vocational or technical education program; and 33% had not participated in any postsecondary training (Shattuck et al. 2012).

Additionally, there are high prevalence rates of comorbid mental health conditions among young

adults with ASD, with an estimation of nearly 50% of the population having comorbid anxiety and/or depression (White and Roberson-Nay 2009). Croen et al. (2015) found that adults with ASD have a 117% higher incidence of anxiety, a 123% higher incidence of depression, and an astounding 433% higher incidence of suicide attempts than their peers. Another study found that 66% of a sample of adults with ASD self-reported suicidal ideation, and 35% had plans or attempts at suicide (Cassidy et al. 2014). Based on these data, the mental health challenges that young adults with ASD experience are not only prevalent but alarmingly severe. Hillier et al. (2011) further suggest that anxiety and depression may be closely related to some of the central difficulties of ASD, including poor social communication, difficulty with unexpected changes in routine, and narrow and repetitive interests. As a result of repeatedly uncomfortable and frequently failed interactions, the individual may withdraw from social engagement, thereby losing social networks and supports, and in turn experience more anxiety and depression. The situation can become even more complicated when symptoms of anxiety and depression among the ASD population do not present as they do in the general population, as they can be masked by ASD characteristics such as flat affect and social withdrawal (Hillier et al. 2011).

Current Knowledge

Relationship of Social Skills, Employment, and Well-being

The relationship between social functioning, employment, and psychological well-being can be seen as cyclical. Late adolescence and young adulthood are particular times of vulnerability to mental health challenges, as social demands increase and individuals with ASD are prone to short tenure of employment partly due to poor social and adaptive functioning. Specifically, poor social functioning may present barriers to obtaining and sustaining employment, leading to increased social isolation and decreased opportunities to practice social competence in work,

resulting in increased anxiety and depression (Connor et al. 2019). Pragmatically, poor employment outcomes also present a barrier to independent living and long-term psychological effects and well-being (Howlin et al. 2005).

Indeed, up to 90% of job losses in individuals with disabilities are due to social communication difficulties (Elksnin and Elksnin 2001). Barriers to successful employment in the ASD population include socially inappropriate behaviors, poor hygiene or adaptive behaviors, deficits in theory of mind, executive functioning impairments, difficulties with sensory processing, and inappropriate interactions with individuals of the opposite sex (Howlin et al. 2005). These barriers lead to a disproportionately high unemployment rates among individuals with ASD (Howlin and Moss 2012; Strickland et al. 2013). Even when employed, individuals with ASD are often underemployed, work less hours, receive lower wages, and have fewer responsibilities and opportunities for promotion given their educational backgrounds and hard skills (Taylor and Seltzer 2011). The damage to self-efficacy and mental health implications that result from unemployment and underemployment can be devastating.

Self-efficacy is an action oriented, future-focused construct that gives individuals the confidence to pursue interests, move forward with goals, and manage tasks (Bandura 1997). Self-efficacy is tied to both work and social performance and is inversely correlated with high levels of social anxiety and depression among individuals (Lorenz et al. 2016). Career success leads to increased self-efficacy and ultimately life satisfaction, whereas repeated job failures negatively impact career self-efficacy and consequently life satisfaction. Further, the high rates of co-occurring mental health conditions (e.g., anxiety and depression) among those with ASD are linked to decreased social and employment participation. Nonetheless, the psychological effects of long-term under- and unemployment have not been extensively studied in the ASD population.

Although the literature has yet to identify the causal relationships between social functioning, employment, and psychological well-being in

the ASD population, it is likely that the effects are bidirectional (White and Roberson-Nay 2009), where interventions targeting any one aspect may impact others. Additionally, these factors make adolescence not only a time of vulnerability but also a critical time for intervention to improve psychosocial and vocational outcomes. Thus, the need for interventions and supports to improve postschool outcomes for this population is extremely crucial during the transition years. In particular, soft skills training is especially vital, as social communication and interpersonal skills have been identified as a significant predictor to employment success for persons with ASD (Chen et al. 2015).

Needs for Evidence-Based Employment-Related Interventions

Successful employment not only increases an individual's social status and financial independence but also positively impacts physical and psychological health and improves overall quality of life. However, current trends indicate that young adults with ASD are not often prepared to meet the varying social demands of the work environment due to limited soft skills training and development (Wehman et al. 2015). This has continued to impact chronic under- and unemployment for this population (Seaman and Cannella-Malone 2016). While programs and services have been created to support the growing number of children with ASD, there has not yet been a concerted effort to ensure adequate support for youth with ASD as they transition into adulthood.

Recent legislation, the Workforce Innovation and Opportunity Act (WIOA 2014), calls for "research related to meeting the education and employment needs of eligible youth" and specifically mandates "the development of alternative, evidence-based programs and other activities that enhance the choices available to eligible youth" (WIOA 2014; Sect. 129). While a dramatically large increase in demand for vocational rehabilitation services for young adults with ASD have been well-described (Chen et al. 2015; Shattuck et al. 2012), less scholarly emphasis has been placed on intervention research as it relates to

employment-related training needs. Until recent years, there has been an expansion in the number of employment-related intervention studies, focusing on improving employment-readiness among transition-age individuals with ASD. Specifically, a total of 42 distinct intervention studies have been identified in recent systematic literature reviews (e.g., Anderson et al. 2017; Hedley et al. 2016; Hotton and Coles 2016; Seaman and Cannella-Malone 2016). Despite this expansion of research in employment-related intervention studies for the ASD population, interventions appear to be disproportionately trending towards specific job skills, or hard skills, with interventions in soft skills being less emphasized.

Based on these systematic reviews, employment-readiness training can be further broken into two skill development categories, hard skills and soft skills, which are both necessary components of obtaining and maintaining employment. *Hard skills* are technical skills and abilities that allow an individual to perform a particular task or activity within a specific context (e.g., developing a resume, using technology to apply for jobs, creating a spreadsheet, organizing merchandise, using computer software, performing clerical tasks, etc.); *soft skills* are intra- and interpersonal qualities that are transferable across contexts (e.g., social-communication skills, positive attitude, responsibility, problem-solving, flexibility, time and stress management, networking, teamwork, work ethic, professionalism, etc.).

Work-related social skills, or soft skills, are facilitators to employment acquisition and central to long-term workplace success (Seaman and Cannella-Malone 2016). While social and psychological difficulties are central to ASD (Hillier et al. 2011), recent research studies reveal that soft skills training and development is a recognized need by both individuals with on the autism spectrum and stakeholders (Seaman and Cannella-Malone 2016) to mitigate the employment situations and potentially improve the psychological well-being among the population. Yet, such intervention studies are scant and only two vocational social skills programs that specifically address both vocational and psychological functioning

for young adults with ASD have been identified (Hillier et al. 2011; Connor et al. 2019) to date. Further, there is limited research describing the relationship between soft skills training, psychological well-being, and employment outcomes for the population (Connor et al. 2019; Sung et al. 2018). Therefore, interventions designed to address workplace social functioning may be particularly relevant to addressing the psychosocial and employment needs of young adults with ASD (Chen et al. 2014).

Existing Interventions that Targets Employment-Related Social Skills

In a systematic review of the ASD literature, Spain and Blainey (2015) found preliminary and promising evidence that group-based social skills interventions for adults with ASD are “effective for enhancing social knowledge and understanding, improving social functioning, reducing loneliness and potentially alleviating comorbid psychiatric symptoms” (p. 874). Below is a summary of some existing intervention programs targeting social skills and/or work-related social skills for young adults with ASD.

Program for the Education and Enrichment of Relational Skills (PEERS)

Laugeson et al. (2015) studied the effectiveness of a social skills curriculum, PEERS for Young Adults, which is built on the manualized PEERS for Adolescents Program, with additional content focusing on dating etiquette, managing peer pressure, and using social goals to improve motivation and compliance. The program is designed for young adults with ASD between 18- and 23-years-old who attend with their social coach (e.g., parent or caregiver) Small groups of 6–8 participants attend 16 weekly group sessions for 90-min per session. Participants are taught social skills through didactics, role-play, and skill practicing during group socialization activities, while social coaches attend separate sessions simultaneously to learn how to provide coaching to young adults in handling social situations. Topics in the curriculum include: developing and maintaining friendships, conversational skills,

entering and exiting conversations, appropriate use of humor, electronic communication, dating skills, organizing get-togethers, handling bullying, handling disagreements, and handling dating pressure.

Gantman et al. (2012) demonstrated that social skills training using the PEERS for Young Adults curriculum resulted in significant increases in social skills knowledge and behaviors, empathy, and social contacts, as well as decreased ASD symptoms and loneliness for participants with ASD. More recently, in a replication study, McVey et al. (2016) found that, in addition to the improvements revealed by Gantman et al., participants also showed significant reductions in social anxiety. However, programs like PEERS focus broadly on general social functioning, including friendships, social gatherings, and effective conversation, which precludes an exclusive focus on developing work-related social skills.

Aspirations Program

Hillier et al. (2007, 2011) studied the effectiveness of the Aspirations program, which is a social and vocational support group consisting of eight weekly sessions for 1 h per session with small groups of between 5 and 7 participants. The curriculum focuses on improving social and vocational skills and covered topics include: introductions, social communication, relationships, independent living, independence and college, and employment. The program uses a discussion-based format designed to be directed by the group members, with the group facilitators simply guiding the discussion and ensuring participants remained on topic. Each session began with a group facilitator introducing the topic for that session and areas to be covered and ended with a review of topics covered and a reflection of learned content.

Hillier et al. (2007, 2011) found that the Aspirations program had positive impacts on empathy, attitudes towards peers, improvements in autistic features, and reductions in feelings of anxiety and depression in participants with ASD. The group members learned and gained greater understanding by sharing personal experiences and listening to those of others, giving each other advice, and

creating problem solving strategies as a group. However, the program was more of a support group rather than a structured learning approach targeting employment or soft skill development through skills training.

Job-Based Social Skills (JOBSS) Program

Gorenstein et al. (2020) evaluated the effectiveness of the JOBSS intervention, which is a manualized, 15-week, group-delivered intervention for small groups of 5–6 young adults with ASD that merges job training and social skills intervention and aims to increase the social-pragmatic skills necessary to obtain and maintain employment. The JOBSS curriculum is fully manualized and includes session-by-session scripts and accompanying worksheets and visual aids. Topics in the curriculum include: active listening, nonverbal communication, theory of mind, making a good impression, identifying emotions, managing stress, problem solving and teamwork, talking about our weaknesses, conversation skills, communication and workplace hierarchy, before and during the interview, ending the interview and afterwards, disclosure, and the hidden curriculum. The curriculum was created to be accessible and easy for those without specialized training to implement using a cognitive-behavioral therapy treatment modality (e.g., conducting structured sessions, connecting cognition to behavior, focusing on the present).

Gorenstein et al. (2020) showed that after completing the JOBSS curriculum, the participants with ASD, as reported by caregiver, demonstrated significantly improved social cognitive skills, and approximately half of participants reported a job obtainment 6 months later. All participants were satisfied with the intervention and were highly likely to recommend the program. The authors suggest that the JOBSS curriculum has potential to improve social skills of adults with ASD, thereby increasing successful employment.

Assistive Soft Skills and Employment Training (ASSET) Program

Sung et al. (2018) examined the preliminary efficacy of ASSET, a soft skills intervention, on

social functioning, self-efficacy, and psychological wellness for young adults with ASD. ASSET is a manualized, group-based intervention that is delivered in school or community-based settings with small groups of 6–8 participants. The originally piloted program was 8 weeks, one session per week, at 90-min each. However, the current program consists of 12 weeks, given added topics per stakeholder's recommendations. The curriculum covers six core work-related social skills, or soft skills: communication, attitude and enthusiasm, teamwork, networking, problem solving and critical thinking, and professionalism, as well as additional topics on mental health and stress management, awareness of self and others, time management, and organization and planning. Ten primary teaching strategies are integrated across sessions, including: didactics, modeling, group discussion, video examples, experiential activities, role-play, self-reflection, performance feedback, positive reinforcement, and generalization. Moreover, ASD-specific pedagogies are used throughout the curriculum, including structured-learning approaches, social performance training, and video-based instruction. The intervention is consistently held in conference rooms (as opposed to classrooms or clinics), and group socialization opportunities are created for participants to practice skills through interacting with peers under the guidance of group facilitators to promote generalization of learning.

Sung et al. (2018) revealed that young adults with ASD not only showed significant improvements in work-related social skills knowledge and social cognition, but their social and empathy self-efficacy improved through experiences of successful, scaffolded learning during the ASSET program. The participants and group facilitators also reported high satisfaction with program activities, training modalities, frequency, and duration of the intervention. Subsequently, Connor et al. (2019) extended the study and indicated that participants' social skill acquisition and augmented self-confidence result in improved psychological wellness, with significant reductions in anxiety and a trend toward lessening depressive symptoms among young adults with ASD.

Virtual Reality Training Programs

Kandalafi et al. (2013) investigated the feasibility and effectiveness of Virtual Reality Social Cognitive Training (VR-SCT). Young adults with ASD who completed the training showed improved theory of mind and emotion recognition. In another study applying virtual reality approaches to teaching interview skills, young adults with ASD who completed the Virtual Reality Job Interview Training program (VR-JIT) showed improved interview skills and self-confidence (Smith et al. 2014). While these studies highlight the effectiveness of using technology to teach skills, as training is individually completed on a computer, neither intervention is integrated in the community, where interviews and employment most often occur.

Future Directions

Research underscores the prevalence and magnitude of issues related to employment-related social competence among young adults with ASD, as well as the potential to utilize group interventions to partially address psychological wellness in addition to the more traditional, individual, clinical, and/or pharmaceutical approaches. The group-based training format offers individuals with ASD not only the opportunity for vicarious skills acquisition and practices with peers, but establishes the sense of belongingness that comes from being part of a group with shared experiences (Connor et al. 2019). The opportunity to share experiences and strategies and to develop relationships with peers who encounter similar challenges may have psychosocial impacts on the ASD population (Hillier et al. 2011). Thus, practitioners working with this population should keep in mind the secondary psychological benefits associated with soft skills interventions, particularly those that are group-based. In addition to more targeted mental health approaches, soft skills training programs may be considered an integral part of promoting, maintaining, and improving psychosocial functioning for young adults with ASD.

While interventions targeting employment-related social skills have been increasingly

prevalent for addressing the pressing soft skills and mental health needs of the larger ASD population, only very few programs are found to be theory-driven and/or possess empirical rigor such as using random assignment and experimental control. Additionally, to date, research has not systematically examined soft skills interventions and its psychosocial benefits as evidence-based practices for young adults with ASD. To better understand the vocational and psychosocial impacts of novel soft skills interventions, rigorous research on the efficacy and effectiveness is essential to ensuring that programs are suited to the population in natural contexts for improving the employment, independent living, and mental health disparities experienced by this population. In addition, continued research should focus on manualized soft skills training curricula. The provision of an empirically validated manual is particularly important because it provides reassurance to practitioners that the intervention can be delivered with in a standardized approach with ease and consistency. Furthermore, manualization not only aids practitioners in the delivery of the intervention, but also aids researchers by providing additional assurance that the intervention is delivered with fidelity. These steps all contribute to ensuring safe, efficacious, and effective programs.

Although randomized controlled trials have been conducted in some of the employment-related social skills interventions, they are largely tested within a single site. Future studies using multisite randomized controlled trials guided by implementation science (Locke et al. 2016) are critical to determine the most efficient and effective ways of implementing soft skills training and psychosocial supports in various environments, such as school or community-based settings. This way, young adults with ASD can benefit from the opportunities for practicing skills within natural contexts to generalize social skill performance. Implementation science emphasizes the need to use evidence-based practices to embed an established practice within an existing entity (e.g., school or community-based settings). It examines the factors, processes, and strategies that influence the uptake, use, and sustainability

of empirically supported interventions and/or practice innovations in routine practice settings. Integrating implementation science into intervention research can advance our efforts to bring research and practice closer together. Further, implementation science can be combined with the recent recommendations for ASD interventions to collectively inform the development process of a usable and acceptable intervention that is designed for implementation and scaling with fidelity by a variety of educational and vocational professionals in a wide range of academic, community, and clinical settings.

Despite the growing number of intervention research focusing on employment-related social skills, there is sparse research on validated measures for assessing specific soft skills, and even fewer instruments have been designed for and/or validated with individuals with ASD (Hedley et al. 2016; Strickland et al. 2013). Perry and Felce (2015) conducted a thorough review and identified 21 published instruments that measure employment-related social skills. Only one instrument is dedicated for vocational social skills assessment, whereas the rest are either too broad with limited focus on specific employment-related social skills or only applicable to children. Thus, research is warranted to develop measures that capture changes in work-related social function among the transition age population. Moreover, many of the current social skills measures are subjective self- or informant-report. Use of video data collection should be further explored as a potentially more direct approach to subjective observational rating.

In sum, the transition from secondary education to higher education, work, and independent living is a critical period in the development of all youth, and one that elicits unique challenges for young adults with ASD. Social isolation and co-occurring mental health problems make this population particularly at risk for service disengagement after high school. The research literature is replete with descriptions of disparate postsecondary outcomes for young adults with ASD, yet evidence-based soft skills interventions are lacking. As a result, it is imperative to develop a larger and stronger evidence base of transition

practice by validating manualized, group-based soft skills interventions that can be easily implemented by practitioners, embedded into multidisciplinary community contexts, and made accessible to young adults with ASD who may otherwise not receive services to address their social and emotional needs. Recognizing the potential bidirectional relationships between work-related social functioning and psychological wellness, more research is needed to inform how soft skills training will address psychosocial adaptation and functional and employment outcomes for young adults with ASD.

Definition

Barker provides a concise and pragmatic conceptualization of psychotherapy, defining the process as a psychological treatment of life problems. Of interest are four added caveats: the treatment must be provided by a trained

practitioner; treatment must occur as part of a professional relationship between provider and patient; treatment must attempt to remove, attenuate or change the life problems; and the process must involve the genesis or nurturance of adaptive behavior and/or personal growth (Barker 1999).

While there are multiple theoretical orientations within the realm of psychotherapy, treatments based upon behavioral and cognitive-behavioral theories have emerged as having the strongest evidence base. These treatments are provided under an array of titles (e.g., self-instructional training, problem-solving therapy, social skills training, and exposure therapy). However, a common thread among all of these psychotherapy programs is their grounding in empirically derived models which explain problem behaviors by way of focusing upon cognitive, emotional, and/or behavioral responses.

In and of itself, a diagnosis of ASD indicates the presence of persistent deficits in communication and social interaction, as well as restricted and/or repetitive patterns of behavior, interests, or activities (American Psychiatric Association [DSM-V] 2013). As such, psychotherapy protocols have been modified to accommodate the need for foundational skill building in these areas. However, a growing literature indicates that patients with ASD are also at high risk for comorbid mental health conditions, including anxiety, depression, bipolar disorder, aggressive behavior, and eating disorders (e.g., Anderson and Morris 2006; Brereton et al. 2006; Gilliot et al. 2001). Notably, such conditions are often more problematic to the child and his/her family than are the core ASD symptoms per se. Because of this, psychotherapy protocols have been developed targeting the specific elements of comorbid conditions.

Historical Background

Studies examining the effectiveness of various types of psychotherapy in typically developing youth with various presenting disorders are numerous (e.g., Abbass et al. 2006; Churchill et al. 2001; Haby et al. 2006; Leichsenring et al.

2004; Smith et al. 1980). In the case of ASD, however, there are multiple issues limiting extrapolation from these studies to youth with ASD and the respective co-occurring condition. Specifically, changes over time in how the etiology of ASD has been conceptualized – from willful withdrawal by the child and poor parenting practices to the contemporary position of a neurobiological etiology – affect the perceived need for psychotherapy, as well as the ultimate goals of such treatment.

Perhaps the first example of such change, and its impact upon psychotherapy as treatment, lies with Kanner's appropriation of the term "autism." Bleuler (1911) used the term to describe a pathognomonic feature of childhood schizophrenia; specifically, a willful withdrawal by the child into their fantasy world. In contrast, Kanner (1943) emphasized the inability of children with autism to use and/or recognize situational, environmental, or social cues.

Kanner went further by linking autism to a lack of familial warmth, although this did not account for asymptomatic siblings of children with autism. The subtle shift from motivational deficit to skills deficit takes on significance when juxtaposed against the prevailing Freudian theory of the 1940s and 1950s, wherein the etiology of ASD was conceptualized as a fundamental lack of parental love and attention, such that healthy interpersonal relationships were unable to be formed or developed by the child. Accordingly, psychotherapeutic treatment consisted of removing the child to a foster home for recovery.

While Freud's theory had little empirical or heuristic value, the notion of parental causation as a determinant in ASD etiology continued into the 1960s and 1970s. It is at this juncture that Bettelheim (1967) compared autism to being imprisoned in a concentration camp and directly linked indifferent mothers to its etiology. This conceptual shift did not affect the core belief that autism is a skills deficit; instead, Bettelheim asserted that these deficits were inflicted by the mother rather than via passive family dynamics. For the next two decades, therapeutic intervention continued to involve removal of children from

their homes; the children were increasingly sent to Bettelheim's institutions to receive "intensive" treatment, typically involving pharmacotherapy (including untested pharmacological agents such as D-lysergic acid diethylamide [LSD]), electric shock therapy, and aversive behavioral conditioning.

Interestingly, it was aspects of behavioral-based psychotherapy used to address problem behaviors among youth with ASD which began to show positive treatment outcomes. The first such techniques were pioneered by Lovaas and colleagues (e.g., Lovaas et al. 1973) and consisted of a comprehensive functional behavior analysis to identify problematic behaviors, task analysis to generate an incremental learning path, and use of shaping to reward progress toward displaying the desired behavioral routines. Taken as a whole, this treatment package represents the first known instance of early intensive psychotherapeutic interventions, wherein behavioral methods were used to instill and develop positive behaviors needed by the child, while simultaneously decreasing or extinguishing negative or challenging behaviors. Although more than 40 years have elapsed since these techniques were introduced for children with autism, they remain highly effective for skill-building and management of undesirable behaviors (e.g., Matson and Smith 2008; Sofronoff and Beaumont 2009).

Beyond changes in conceptualization, the issue of psychotherapy effectiveness is further clouded by the observation that the social, emotional, and behavioral skills commonly found to be impaired among children with ASD (e.g., Brereton et al. 2006; Cohen and Volkmar 1997; Myers et al. 2007) are the foundational skills for most forms of psychotherapy (Cashin 2008). As a result, the magnitude of such deficits is a key prognostic indicator for children (Mackay et al. 2007) and is commonly integrated into psychotherapy addressing higher-level skills and/or comorbid deficits.

In addition to aggressive and/or disruptive behavior management, attempts to address social skills deficits in children with ASD are numerous (e.g., Kamps et al. 1992; Koegel et al. 1992;

Krasny et al. 2003; Ozonoff and Miller 1995; Parsons and Mitchell 2002; Paxton and Estay 2007); however, the findings from most evaluative studies indicate that traditional social skills training shows relatively limited outcomes for children with ASD. Specific criticisms include the following: most programs are intended for application with various populations of neurotypical children (i.e., not children with ASD); a fundamental lack of agreement as to what constitutes the group of behaviors considered necessary for social skills training; lack of techniques to promote or monitor generalization of acquired skills throughout the course of the curriculum and beyond; and a failure to consider and account for variability in cognitive functioning of target children (e.g., Rao et al. 2008; Reichow and Volkmar 2010; White et al. 2007).

More recent studies have addressed comorbid anxiety and problems with social functioning in children with ASD, typically through using specific techniques (e.g., small group exercises, increasing structure within all activities, and parent training) within a more typical cognitive-behavioral therapy framework. Examples include "Exploring Feelings: Cognitive Behavior Therapy to Manage Anxiety" (Attwood 2004), "Facing your Fears" (Reaven et al. 2012), and "Behavioral Interventions for Anxiety in Children with Autism" (BIACA; Wood and Drahota 2006; Wood et al. 2009a). While maintaining a focus similar to psychotherapy for typically developing children (e.g., exposure, emotion recognition, cognitive therapy, and relaxation), these programs also include specific strategies designed to address skill deficiencies common among children with ASD (e.g., nonverbal communication, prosocial behaviors, emotional regulation, and perspective taking).

Current Knowledge

Relative to the general pediatric population, children with ASD are at a heightened risk for certain comorbid mental health conditions, such as anxiety, depression, externalizing behaviors,

eating disorders, and/or bipolar disorder (e.g., Anderson and Morris 2006; Brereton et al. 2006; Gilliot et al. 2001). As mentioned earlier, cognitive-behavioral psychotherapy shows strong empirical support for the treatment of symptoms used as diagnostic markers for ASD, as well as for associated comorbid conditions (e.g., Chambless and Hollon 1998; Kazdin and Weisz 2003). As such, it became necessary to modify traditional cognitive-behavioral techniques to address the particular combination of diagnostic symptoms and comorbid conditions in children diagnosed with ASD (e.g., Attwood 2003, 2004).

Examination of treatment elements of cognitive-behavioral therapy for neurotypical youth reveals some commonality across targeted problems. For example, cognitive-behavioral therapy for anxiety disorders (e.g., Wood and McLeod 2008; Wood et al. 2006) includes affective education, exposure therapy, cognitive restructuring, contingency management, and problem-solving. Cognitive-behavioral treatments commonly used for most presenting concerns contain some or all of these elements (e.g., Anderson and Morris 2006). Therefore, any necessary modification to such programs for children with ASD is related to previously mentioned social, emotional, and cognitive deficits rather than to the comorbid conditions (Paxton and Estay 2007; Shapiro 2009).

Extending this idea can provide guidelines for determining the appropriateness of psychotherapeutic intervention. For example, the psychotherapy protocol must account for the child's language and cognition skills; specifically, that their skills are sufficiently advanced to allow for meaningful discourse within session. If these skills are not sufficiently developed, then the protocol must include contingencies for building and generalizing such skills. A reluctance to speak or participate may be addressed through improving rapport and information sharing with the parents such that more information is gained about the child for use in session (e.g., increasing relevance of materials, rapport building through common interests). Similarly, positive reinforcement methods (i.e., shaping) may be used to address reduced language skills. Further, a mechanism for increasing the child's awareness

and self-reflection must be included to allow for generalization of new skills to novel situations (Shapiro 2009).

To date, there are relatively few randomized clinical trials examining the use of various forms of psychotherapy among children with ASD; however, the studies available are promising including a recent large-scale study (Wood et al. 2019). For example, a meta-analysis of studies using manualized psychotherapy protocols for children with ASD and comorbid anxiety reported significant reductions in anxiety symptoms, increased independent living skills, increased usage of adaptive coping strategies, and improved quality of life (Sukhodolsky et al. 2013). A preliminary examination of intensive (daily) psychotherapy addressing comorbid obsessive-compulsive symptoms among youth with ASD reported similar positive responses and gains related to adaptive functioning (Iniesta-Sepulveda et al. 2018). While generally similar to psychotherapy for children without ASD, these protocols typically are more intensive with respect to foundational skill building to address presumed deficits in cognitive, social, and emotional functioning (e.g., Wood et al. 2009a).

Future Directions

Although a growing research base exists supporting the utility of psychotherapy for social and behavioral problems among children with ASD, there remains a need for investigation into the efficacy of psychological treatments for adolescents with similar comorbid diagnoses. Though preliminary, a few studies provide support for effectively addressing comorbid anxiety symptoms among adolescents with ASD (e.g., Storch et al. 2015; Wood et al. 2015). These protocols place an emphasis upon social situations and basic skills unique to adolescent populations (e.g., social coaching to address adolescent peer relationship building, emotional regulation with respect to peer harassment/bullying, and independent living skills) in addition to core CBT elements (e.g., exposure).

Ultimately, the true measure of success for psychotherapy in children and adolescents with

ASD will be the degree to which treatment outcomes are clinically meaningful and translate into changes in functioning and quality of life. Some preliminary results suggest that psychotherapy incorporating in vivo exposure is superior to waitlist controls with respect to improvement in parent-reported social responsiveness, and that psychotherapeutic gains are durable over the short term (e.g., Wood et al. 2009b). As well, it remains to be seen how evidence-based forms of psychotherapy fare in randomized clinical trials against both pharmacological and exclusively behavioral techniques.

Psychosis; Schizophrenia

Definition

Psychotic disorders are a group of psychiatric disorders in which distortion of reality and severe disorganization are present. Reality distortions include hallucinations, which include sensory experiences in the absence of external stimulation that appear real, and delusions, false beliefs that persist, despite evidence to the contrary. Disorganization can be reflected in speech, thought, or in behavior. According to the DSM-IV-TR (American Psychiatric Association 2000), the psychotic disorders include schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, brief psychotic disorder, and shared psychotic disorder. In addition, psychotic disorder can be diagnosed due to a general medical condition or as a substance-induced disorder. A diagnosis of psychotic disorder not otherwise specified indicates that there is not enough information to make a more specific diagnosis or that there are insufficient symptoms to meet the criteria of one of the specific diagnoses. The lifetime prevalence of psychotic disorders in the general population is estimated to be about 2%.

To receive a diagnosis of schizophrenia, an individual must present with two or more of five characteristic symptoms including delusions, hallucinations, disorganized speech, disorganized or catatonic behavior, and negative symptoms. Negative symptoms include dulling of affect and avolition which is a lack of self-directed behavior. The onset of schizophrenia can be slow and gradual or can be acute. There must be social or occupational dysfunction, and the duration of the symptoms must be at least 6 months. The course of the illness can present as a single episode, multiple episodes, or continuous.

There are several subtypes of schizophrenia that are defined based on the prominence of specific symptoms. The subtypes include paranoid, disorganized, catatonic, undifferentiated, and residual type. The committee for the development of the DSM-V has considered removing the subtype distinction due to relative instability of categorization across time and questionable validity (American Psychiatric Association 2010). If there is a history of autistic disorder or pervasive

developmental disorder, the DSM-IV-TR states that a diagnosis of schizophrenia can be made only if there are prominent delusions or hallucinations that are present for at least a month (or less if it is successfully treated). To receive a diagnosis of schizophreniform disorder, the individual must have symptoms of schizophrenia without a functional decline, and the episode is of short duration from 1 to 6 months.

In schizoaffective disorder, there are characteristic symptoms of schizophrenia along with either a depressive, manic, or mixed mood episode. The mood disorder must be present during much of the illness.

In delusional disorder, there are nonbizarre delusions of at least 1-month duration. Unusual behavior is directed toward the delusions. Hallucinations, if they occur, are related to the delusions. The individual's functioning is not significantly impaired.

In brief psychotic disorder, the symptoms last between 1 day and 1 month. Full recovery is the typical outcome.

Shared psychotic disorder occurs when one individual shares a delusion that is maintained by another individual. The symptoms are usually grandiose or paranoid.

Infantile psychosis and early childhood schizophrenia at one time were terms used to describe autism. Kanner (1949) stated that autism would likely be determined to be an early type of schizophrenia. In later years, Rutter (1972) distinguished between autism and schizophrenia based on a number of factors such as age of onset and the course of the disorders. Case reports of individuals diagnosed with autism in childhood and found to be diagnosed with psychotic disorders as adults raised the question of whether autism in childhood increases the likelihood of psychosis in adult life (e.g., Clarke et al. 1999). Based on a larger study group of well-documented cases, Volkmar and Cohen (1991) found that the frequency of schizophrenia in autism is comparable to the general population (about 1%).

Individuals with ASD may be misdiagnosed as psychotic if there is an appearance of a thought disorder. The presence of a thought disorder is evidenced by bizarre, disorganized, or

idiosyncratic speech. Individuals with ASD may have unusual interests and ways of expressing themselves verbally. They use language concretely and have difficulty describing abstract or emotional concepts (Howlin 1997).

Significant impairments in language and cognition occur commonly in autism spectrum disorders which poses a challenge to the accurate diagnosis of psychiatric disorders. The DM-ID was developed jointly by the American Psychiatric Association and the National Association for the Dually Diagnosed (2007) to address the difficulties inherent in making psychiatric diagnoses with persons with intellectual disability. The DM-ID suggests adaptations to the DSM-IV-TR. The adaptations include using reports from others as a substitute for self-report and reducing the number of required symptoms for making a diagnosis if the individual is nonverbal. In the case of the psychotic disorders, the DM-ID notes that engaging in self-talk is relatively common in individuals with intellectual disability and it should not be interpreted as a symptom of psychotic disorder (p. 150).

Psychotic Symptoms in Autism

Zheala Qayyum

Department of Psychiatry, Yale University,
New Haven, CT, USA

Definition

Autism spectrum disorders are neurodevelopmental disorders that in DSM-V are characterized by impaired social interaction and communication, as well as restricted interests and repetitive behaviors. In addition, individuals diagnosed with ASD may exhibit broader phenomenology including psychotic symptoms. The presence of psychotic symptoms in ASD is a substantial source of morbidity, often being a reason for both hospitalization and the prescription of antipsychotic medications. The relationship between autism spectrum disorders and psychosis is both complex and interesting. Differentiation of these conditions, accurate diagnosis, and appreciation of the comorbidity is often challenging in the light of significant clinical overlap.

ASD and psychotic disorders have overlapping clinical phenomenology, neurobiology, and genetic risk factors. Further, studies have found higher prevalence rates of psychotic disorders, in addition to schizophrenia, in individuals with ASD as compared to the general population. Overall, research in the field of childhood neurodevelopmental disorders has identified evidence for a connection between developmental

disorders that manifest in childhood and the subsequent risk of psychotic experiences in adolescence.

Historical Background

There has been significant appreciation of the complexity and distinctive states of psychotic disorders and autism leading to a shift from how they were historically conceptualized. Bleuler categorized autism as a core feature of schizophrenia (Bleuler 1950) and Bender described autism as childhood onset schizophrenia (Bender 1947). Kraepelin (1971) had also recognized that many children who went on to present with dementia praecox “exhibited a quiet, shy, retiring disposition, made no friendships, lived only for themselves.” In adulthood, these individuals often received the diagnosis of schizoid or schizotypal personality disorders which themselves are associated with the risk of later development of schizophrenia. In the 1970s, Autism began to emerge as a separate condition, the distinction based more so in terms of an early age of onset for ASD and led to its official acknowledgement as a separate disorder in DSM-III. In 1972, Rutter addressed the confusion between these conditions and the way the term childhood schizophrenia was applied to various other conditions leading to the change in terminology.

Clinically, the neural deficits of schizophrenia are present earlier during development; however, symptoms of schizophrenia such as behavioral disorganization, delusions and hallucinations, apathy, and amotivation often present later in adolescence or in early adulthood (Lieberman 1999). Even in the case of childhood onset schizophrenia, formative accounts described a psychotic syndrome with a clear age of onset (Kolvin et al. 1971; Russell et al. 1989). However, symptoms of autism spectrum disorders are thought to manifest themselves from the very early periods of development and have a more persistent course (Kanner 1949).

Despite this important distinction, there are nevertheless challenges in differentiating these disorders. A number of adults with psychotic illness have some history of ASD-like symptoms in

childhood, a finding that some have described as indicating “a non-specific marker of severe early abnormal neurodevelopment” (Sporn et al. 2004). Shared genetic and neurodevelopmental processes underlying both conditions were highlighted in the evidence reviewed by Rapaport et al. (2009). In support of this perspective, a study by Sullivan et al. (2013) reports on a large cohort where a diagnosis of ASD was found to predict future psychotic experiences. It also highlights that the relationship between these conditions is further complicated by the hypothesis that there may be “an artificial overlap” between COS and ASD due to the “similarities in descriptive phenomenology.” Particularly, the social deficits in ASD may appear similar to negative symptoms of schizophrenia, and furthermore, recent work has found that psychotic experiences can co-occur with ASD, though this may also reflect concrete responses to probes regarding psychiatric symptomatology (Sullivan et al. 2013). Other areas where this overlap is evident include theory of mind problems, behavioral problems, and language difficulties (Fitzgerald 2012). The heterogeneity and spectrum of etiology and presentation of these disorders are a very important consideration when drawing and in the future redrawing diagnostic boundaries between these conditions.

Current Knowledge

There are unique challenges involved in attempting to diagnose psychotic symptoms in autism spectrum disorders. Experimental evidence highlights meaningful distinctions and consistencies between psychotic disorders and ASD. There is evidence for disruption of embryonic brain development in both ASD and psychosis (Delacy and King 2013). The NMDA receptor function and glutamate signaling pathway disruptions have been implicated in the pathophysiology of schizophrenia and ASD. There are particular areas of neurodevelopmental deficits that are shared between ASD and psychosis, such as deficits in theory of mind, functional deficits in the mirror neuron system, and abnormalities in the functional connectivity of the brain. The study by Walter et al. (2010) highlights theory of

mind, mirror neuron, and functional connectivity deficits in a sample of healthy volunteer subjects identified via the presence of the psychosis risk allele variant of the ZNF804A gene. The genetic overlap between the two continues to be explored, as evident in the two large case-control studies which have shown that parental schizophrenia is a significant risk factor for autism (Larsson et al. 2005; Daniels et al. 2008). Rapoport et al. (2009) also highlight the growing weight of evidence from candidate gene, linkage, and expression studies, and copy number of variants that appear to be shared in both autism and schizophrenia. The velocardiofacial syndrome (chromosome 22q11) deletion shows high rates of childhood ASDs (30 [50%] of 60) and psychotic symptoms (16 [26.7%] of 60). Although a study of common single-nucleotide polymorphisms found only a low genetic correlation between ASD and schizophrenia (Vorstman et al. 2013). Deletions, disruptions, and missense mutations in neurexin 1 (NRXN1) have been reported recently in several cases with autism (Marshall et al. 2008; Kim et al. 2008; Zahir et al. 2008; TAGP Consortium 2007; Feng et al. 2006; Weiss et al. 2008) and two cases with schizophrenia (Kirov et al. 2008; Zoghbi 2003). Additionally, certain risk factors are also shared by ASD and psychosis such as high paternal age, obstetric complications, and maternal infections.

Brain imaging studies in autism show increased head size/total brain volume seen in the first 3 years of age based on cross-sectional studies (Hazlett et al. 2005). By contrast, COS studies demonstrate loss of cortical gray matter in early ages that progresses through adolescent years, which seems to be an exaggeration of the normal pattern of cortical brain development. It may be surmised that in ASD there is an acceleration of early postnatal brain development when compared to COS demonstrating exaggerated brain maturation in childhood and adolescence. With respect to normal brain development “both patterns may be seen as an abnormal shift to the left with autism showing initial overgrowth and COS showing greater pruning down of cortex in early and middle part of the trajectory, both accelerations normalizing with age” (Rapoport et al. 2009).

In regard to pharmacological treatment, antipsychotics are the most commonly prescribed class of medications for ASD (Hsia et al. 2013). While the use of antipsychotics has been the mainstay of treatment of psychotic disorders, the FDA-approved medications for treatment of aggression associated with ASD are also antipsychotic agents such as risperidone and aripiprazole. There is a growing interest in the modulation of the glutamatergic signaling pathways by these agents and their efficacy in both ASD and treatment of psychotic symptoms.

However, the presentation of psychotic symptoms can be highly variable in ASD. A recent study of a dually affected cohort of patients with ASD (Larson et al. 2017) found significant differences in the autistic phenotype of patients who had comorbid psychotic illness compared to those with ASD alone. Those with comorbid psychotic illness showed fewer lifetime stereotyped, repetitive, or restrictive interests/behaviors, with greater diagnosis of psychosis NOS and lower rates of diagnosis of schizophrenia.

The evidence around the phenomenology of psychotic symptoms in ASD remains limited and unsystematic pointing to the possibility of further subtypes of individuals with ASD with psychotic comorbidity. One possibility proposed is the subtype of ASD that carries a higher risk of psychotic illness mediated by common genetic variants. In this case, significant differences would be anticipated in presentation of ASD features in patients with ASD with psychosis than ASD patients without psychosis, and that the psychotic symptoms would be similar across people with ASD (Larson et al. 2017; King and Lord 2011). The other consideration is of misdiagnosis of features of ASD as psychosis (Van Schalkwyk et al. 2015; Lai and Baron-Cohen 2015) given difficulties with theory of mind and reading other people's intentions that may resemble paranoia, expressive communication difficulties that can be mistaken for thought disorder and “melt downs” that resemble catatonia. It can be hypothesized that individuals with ASD may experience some degree of delusions without the presence of any additional impairment, but that hallucinations are likely indicative of a distinct process (Van Schalkwyk et al. 2017).

Diagnosing psychotic symptoms in an ASD patient also is complicated by factors such as deficits in language and a tendency towards concrete responses. Furthermore, “these psychopathological alternatives might simply be epiphenomena of different constructs and language from separate literatures applied to the same mental phenomena” (Larson et al. 2017), such that the experiences of the individuals with ASD can fit as part of both categories of ASD and psychosis.

Finally and very importantly, there are additional psychosocial stressors that are compounded by the stress resulting from the impairments associated with ASD that can elevate the risk for developing psychotic symptoms, such as social exclusion, which is common in ASD, has been hypothesized to be an important risk factor for nonaffective psychotic disorders (Selten et al. 2015; Gevonden et al. 2014). During adolescence, many psychiatric illnesses are likely to have their initial presentation, increasing the pertinence of this consideration. As these individuals undergo the transition from late adolescence to early adulthood there is an additional risk of substantial change as they may lose the support of entitlements and treatment networks that were available to them at younger ages (Volkmar et al. 2014). The effects of these changes may be that these individuals are seen by adult psychiatrists with comparatively less understanding of their condition, and perhaps more importantly, must interact with a treatment system that is not well-oriented to their needs (Volkmar et al. 2014). Individuals with behavioral problems are at increased risk of being admitted to inpatient units (Tsakanikos et al. 2007). As Kanner himself pointed out, adolescence is a common time during which some individuals with autism would experience deterioration (Kanner 1971) and this is also the typical age of onset of psychotic disorders.

Future Directions

It is evident that individuals with ASD have a higher risk of developing psychotic symptoms and will be treated in medical and mental health settings. It is often the case that the diagnosis of

ASD is made much later or has been overlooked due to several reasons prior to this, leaving the burden of diagnostic clarity and treatment on the shoulders of the clinical team to tease apart the symptoms based on etiology, phenomenology, and appreciation of overlapping presentations. The development of a multidimensional model that helps understand the complexity of these two conditions and expands to encompass affective, psychotic, and autism spectrum characteristics (Larson et al. 2017) will be important in addressing this diagnostic quandary. Further research in genetic markers, clarification of genetic and syndrome heterogeneity, and the population samples that have closer correlation to those seen more commonly in clinical practice will be significant in providing insight into early diagnosis and treatment of this comorbid condition.

Public Law 94-142

Debra Dunn

The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

Public Law 94-142, also known as the Education for All Handicapped Children Act (EAHCA) of 1975, is the landmark federal legislation pertaining to the education of children with disabilities. The law guaranteed a “free, appropriate public education” to all children and young adults aged 3–21. PL 94-142 was an amendment to the Education of the Handicapped Act (EHA) of 1970 and served as Part B of the EHA. Congress has since replaced PL 94-142 with the Individuals with Disabilities Education Act and the Individuals with Disabilities Education Improvement Act, but the tenets of the EAHCA – namely to improve the educational opportunities of students with disabilities – remain intact.

Historical Background

Although considered groundbreaking, PL 94-142 was not the first piece of federal legislation pertaining to the education of students with disabilities. Many pieces of federal legislation beginning in the 1950s had touched on educational issues of students with disabilities, including several portions of bills (e.g., PL 85-926, PL 86-158, PL 87-276, PL 87-715, and PL 88-164), which provided training to teachers of deaf students and students with mental retardation (now called intellectual disability). Additionally, the Elementary and Secondary Education Act of 1965 (PL 89-10) is considered a significant bill pertaining to education because it was the first law to provide federal funding to states for the education of students. (It funded the education of students in specialized state schools for the blind, deaf, and mentally retarded and also provided federal funding to help educate impoverished students.)

The Education of the Handicapped Act of 1970 (EHA) (PL 91-230) was the first federal law to exclusively address the education of children with disabilities. It provided grants to institutions of higher learning to develop programs to train teachers of students with disabilities and funded regional resource centers to deliver technical assistance to state and local school districts. Its first amendment in 1974 mentioned the term “appropriate education” for the first time in federal legislation and added a requirement that states which received federal funds adopt the goal of full educational opportunities for students with disabilities.

Despite the EHA, however, as of 1975, over half of the students with disabilities were not receiving appropriate educational services, including over a million children who were not receiving any public education at all. Many of the students who were receiving educational services received them in institutions far away from their families, at great cost to the families or through the generosity of charities.

Spurred by the civil rights movement and by *Brown v. Board of Education* (1954), which ruled that states must provide equal educational opportunities to children regardless of race, beginning in the 1960s, advocates for students with disabilities began to file lawsuits against their home states and school districts. These lawsuits claimed that exclusion, segregation, and inappropriate educational services for students with disabilities violated the students' rights under the 14th Amendment of the United States Constitution. Cases like *Pennsylvania Association for Retarded Citizens (PARC) v. Commonwealth of Pennsylvania* (1972) were filed by parents of children with disabilities asserting their children's right to a public education.

By 1973, 27 right-to-education lawsuits had been filed on behalf of students with disabilities across 21 states. As a result, the policies being developed across the country varied significantly. While many of the early lawsuits resulted in expanded educational opportunities for children with disabilities, not all lawsuits were won by the students petitioning. Indeed, the combination of district court losses like *Harrison v. Michigan*

(1972) and the United States Supreme Court decision in *San Antonio v. Rodriguez* (1973), a school finance case which held that the Constitution did not establish a right to public education, caused many disability advocates to worry about how the Supreme Court might decide the right to education cases for students with disabilities. Rather than continue to take their chances in the courts, these advocates chose to pursue a legislative agenda.

In addition to the EHA, Congress had already begun to pass several pieces of progressive social legislation, including the Occupational Safety and Health Act of 1970, the Child Development Act of 1971, and Section 504 of the Vocational Rehabilitation Act of 1973, which outlawed discrimination on the basis of disability in programs receiving federal assistance. The climate for an expanded bill related to the education of children with disabilities seemed favorable. Disability and child advocates persuaded Senator Harrison Williams to introduce an amendment to the EHA to ensure that children with disabilities receive a free and appropriate public education (FAPE), to protect the rights of students and their parents, and to assist states in providing educational services to students with disabilities. The legislation was supported by the Council of Chief State School Officers and the National School Boards Association. Indeed, not a single person or organization testified against the bill in Congressional hearings. The bill, which came to be known as the Education for All Handicapped Children Act, or PL 94-142, passed by wide margins. Despite initial resistance by former President Gerald Ford, the President signed the act into law in 1975.

Since the bill's passing in 1975, there have been several amendments to the law. In fact, the laws pertaining to the education of children with disabilities are changed somewhat regularly because portions of the legislation must be reauthorized periodically and because Congress must routinely approve funding. The most significant changes to PL 94-142 include: the Infants and Toddlers with Disabilities Act of 1986 (PL 99-457), which required states to provide programs and services from birth (PL 94-192 only required programs for ages 3–21); the

Individuals with Disabilities Education Act of 1990 (PL 101-476), which changed the name of the law from the Education for All Handicapped Children Act to the Individuals with Disabilities Education Act (IDEA), added two categories of disability – including autism, and supported initiatives for transition to adulthood; the Individuals with Disabilities Education Act Amendments of 1997 (PL 105-17), which strengthened the role of parents, emphasized student progress toward meaningful educational goals, encouraged non-adversarial mediation to resolve disputes, added disciplinary provisions, and made extensive changes to the individualized education plan (IEP); and the Individuals with Disabilities Education Improvement Act of 2004 (PL 108-446), which required the use of scientifically based instructional practices and interventions whenever possible, required special education teachers to be “highly qualified,” revised the discipline procedures, revised dispute resolution procedures, created “early intervening services” to assist students who are struggling but who do not require special education services, reduced paperwork burdens on states and school districts, emphasized student progress and progress monitoring and reporting, and made other changes to the IEP process.

It is important to note that the federal laws pertaining to the education of students with disabilities are subject to state implementation. States are at liberty to provide more rights to students, but cannot provide less than those guaranteed by the federal statute. Each state has its own regulations interpreting and executing the federal law, and thus implementation will vary from state to state.

Current Knowledge

As indicated by the legislative history, the impetus for PL 94-142 was a national recognition of the poor outcomes of children with disabilities due to their unequal educational opportunities and a desire to significantly improve access to education for these children. The law addressed how children with disabilities were identified, how they

would be educated, how to evaluate the success of educational efforts, and how to protect the rights of children with disabilities and their parents. As an improvement on the EHA of 1970, the law authorized significant financial incentives for complying with PL 94-142.

Specifically, the law mandated that “all children with disabilities [must] have available to them . . . a free appropriate public education which emphasizes special education and related services designed to meet their unique needs.” It required that special education and related services for children between the ages of 3 and 21: (1) be provided at public expense; (2) include an appropriate preschool, elementary, and secondary school education in the home state of the student; and (3) be provided in accordance with an Individualized Education Program (IEP) uniquely designed for each student. The federal law also required states to set standards to implement the federal law. Thus, with the passage of PL 94-142, the federal government and the states became partners in the education of students with disabilities.

The concepts arising from PL 94-142 – in particular, the paradigm of a free and appropriate public education, the creation of the individualized education program, and the creation of a federal/state partnership in education – have been expanded upon greatly since 1975. Yet despite frequent litigation over the principles and years of state and federal regulations, PL 94-142 remains the most significant piece of federal legislation pertaining to the education of students with disabilities.

Future Directions

The most current legislation pertaining to the education of individuals with disabilities is Public Law 108-446, commonly referred to as the “Individuals with Disabilities Education Improvement Act of 2004” or “IDEIA.” Other legislation, such as the No Child Left Behind Act of 2001 (PL 107-110) and its subsequent revisions, have also influenced the development of laws pertaining to students with disabilities.

Public Perception of Autism Treatments: Science Versus Pseudoscience in the Age of Mass Media

Veronica P. Fleury and Richard Marks
Florida State University, Tallahassee, FL, USA

Definition

Autism treatments: Strategies aimed at improving outcomes for individuals with autism spectrum disorder (ASD) by teaching compensatory skills, ameliorating the core behavioral characteristics associated with ASD, and/or minimizing the impact of these behaviors on an individual's functioning. Numerous treatments and/or instructional strategies have been presented as plausible approaches to treating autism-related behaviors. The quality and quantity of research supporting a given practice or treatment vary. Strategies deemed *evidence-based practices* are supported by multiple, methodologically rigorous, and empirical research studies. In contrast, *pseudoscientific practices* are unsupported by credible evidence, yet consumers view them as viable treatment options.

Mass media: Technology that is intended to reach a broad audience. The most common platforms for mass media are newspapers, magazines, radio, television, and the Internet.

Historical Background

Autism spectrum disorder (ASD) is a lifelong disorder. Although there is no cure for ASD, behaviors that characterize the disorder can be

amenable to intervention. Education is believed to be “the best hope for improving outcomes for individuals with ASD” (McIntyre et al. 2013). The concept of evidence-based instruction is central to the provision of educational services to children and youth with ASD in the United States. Federal mandates such as the Every Student Succeeds Act (Pub. L. No. 114-95 § 114 Stat. 1177) and Individuals with Disabilities Education Act (20 U.S.C. § 1400 *et seq*) as well as ethical guidelines for special education professionals emphasize that instruction and intervention for students with disabilities be research based (Council for Exceptional Children 2015). Professional guidelines for special education professionals are summarized in Fig. 1.

Evidence-based practices. Multiple workgroups have conducted systematic reviews of autism intervention research to identify effective interventions and discriminate new and promising approaches from the deceptive and improbable. Most notably are the large-scale reviews conducted by the National Standards Project (National Autism Center 2015) and the National Professional Development Center on ASD (NPDC, Wong et al. 2015). The review process includes screening intervention studies for methodological rigor based on criteria established by panels of experts (Horner et al. 2005; Gersten et al. 2005) and design standards from the What Works Clearinghouse (U.S. Department of Education). Studies with strong methodological rigor are then subjected to content analysis in which researchers identify specific components of the intervention. Interventions that have multiple studies that support its effectiveness are deemed *evidence-based practices* (EBPs). The key distinction here is that EBPs have multiple, methodologically rigorous experimental studies, that have been conducted across different research groups.

Although there are differences in how each work group conceptually organized and labeled specific instructional strategies, the majority of the EBPs for individuals with ASD are based on foundational applied behavior analytic concepts (e.g., prompting, reinforcement, task analysis) or organized into multicomponent interventions that

The Council for Exceptional Children (CEC, 2015) identified 12 ethical principles to guide special educators' professional practice. The principles highlighted in bold specifically relate to the use of evidence-based practices:

1. Maintaining challenging expectations for individuals with exceptionalities to develop the highest possible learning outcomes and quality of life potential in ways that respect their dignity, culture, language, and background.
2. **Maintaining a high level of professional competence and integrity and exercising professional judgement to benefit individuals with exceptionalities and their families.**
3. Promoting meaningful and inclusive participation of individuals with exceptionalities in their schools and communities.
4. Practicing collegiality with others who are providing services to individuals with exceptionalities.
5. Developing relationships with families based on mutual respect and actively involving families and individuals with exceptionalities in educational decision making.
6. **Using evidence, instructional data, research, and professional knowledge to inform practice.**
7. **Protecting and supporting the physical and psychological safety of individuals with exceptionalities.**
8. **Neither engaging in nor tolerating any practice that harms individuals with exceptionalities**
9. Practicing within the professional ethics, standards, and policies of CEC; upholding laws, regulations and policies that influence professional practice; and advocating improvements in the laws, regulations, and policies.
10. **Advocating for professional conditions and resources that will improve learning outcomes of individuals with exceptionalities.**
11. Engaging in the improvement of the profession through active participation in professional organizations.
12. Participating in the growth and dissemination of professional knowledge and skills.

Public Perception of Autism Treatments: Science Versus Pseudoscience in the Age of Mass Media, Fig. 1 CEC Ethical principles & practice standards for special educators

P

incorporate foundational concepts (e.g., functional communication training, pivotal response training, naturalistic intervention). In addition, there are a set of practices that have been routinely incorporated into a package of positive behavior intervention and support (e.g., functional assessment, extinction, redirection, antecedent interventions, direct reinforcement of other behavior). It should be noted that the primary target of EBPs are specific skills that will lend to improve outcomes and/or overall functioning. These practices are intended as key elements of instruction, to be implemented consistently and over a period of time. The general goal of any EBP is not to eradicate symptoms or serve as a quick "cure."

Pseudoscientific treatments. Treatments with a basis in pseudoscience offer solutions that are in stark contrast to scientific principles. These treatments typically do not have a foundation based on past scientific findings or controlled studies, are not refined over time as new evidence is disseminated, and either do not contribute to the extant research and/or are incompatible with existing and accepted theories (Mugaloglu 2014). Defining characteristics of pseudoscientific approaches includes the following: a lack of testability, self-correction, and/or peer review, an emphasis placed on confirmation and anecdotal evidence, correlating practices with the past as a means of arguing correctness, overly technical language,

and the presence of extraordinary claims related to the practice in question (Boudry et al. 2015; Lilienfeld et al. 2012). A table contrasting characteristic features of science and pseudoscience can be located in Table 1.

The field of ASD has been concerned with the spread of misinformation for years (Ganz et al. 2018). Facilitated communication (FC), for instance, was a practice that gained popularity during the 1990s through early 2000. FC is an intervention designed to address the complex communication needs impacting many students with disabilities, including ASD. A facilitator provides physical support to assist an individual in selecting words and/or phrases on an augmentative and alternative communication (AAC) device (Ganz et al. 2018). Methodologically rigorous studies that attribute that the supposed effects of improved communication to the facilitator rather than the individual with ASD have been used to debunk the practice. Several professional

organizations have since released position statements opposing the use of FC, including the American Academy of Pediatrics (1998), American Association on Mental Retardation (1994), American Psychological Association (1994), Association for Behavior Analysis (1995), and American Speech-Language-Hearing Association (1995). The use of FC has not been completely eradicated, however, with research documenting that FC use with children with ASD may be as high as 9.8% in some areas. A resurgence believed to be a variation of FC has emerged in recent years, gaining popularity under the guise of rapid prompting methods (Mostert 2001, 2010; Travers et al. 2014). Other popular pseudoscientific ASD treatments include, but are not limited to, sensory integration interventions (e.g., pressure and weighted vests, brushing techniques, vestibular swinging; Barton et al. 2015), learning styles (Pashler et al. 2008), auditory integration training (Simpson 2005), and DIR/Floortime (National Autism Center 2015).

Table 1 Contrasted characteristics of science and pseudoscience

Science	Pseudoscience
Evidence obtained via experimentation informs beliefs; belief in a claim is withheld if evidence is not available; relies on the entire body of evidence	Beliefs are formed first, and evidence is sought to support; relies on credulity; disconfirming evidence is rejected to preserve belief
Makes conservative and tentative claims based on evidence; beliefs change with new evidence; open-minded	Makes sensational claims without evidence; rejects new evidence against belief; clog-minded
Uses precise terminology to aid understanding and independent verification; rejects unverifiable claims	Uses vague language and jargon to avoid criticism and inhibit verification; accepts unverified claims
Knows, understands, and applies the rules of logic with body of evidence to make claims	Uses logical fallacies and cherry-picks evidence to make claims
Treats critics as colleagues and values criticism from a community of scientists; engages in honest debate	Does not value criticism and condemns dissent; works in isolation and dishonestly engages in debate

Travers (2017) Published with permission

Current Knowledge

Pseudoscience is neither a new phenomenon nor unique to ASD. There are, however, factors unique to ASD that may make families and practitioners especially vulnerable to accepting and adopting pseudoscientific practices (Metz et al. 2016). One factor that makes ASD susceptible to attracting pseudoscientific treatments is the absence of a definitive or singular cause of ASD. ASD is identified based on the presence – or absence – of behavioral features, specifically deficits in social communication combined with the presence of restricted, repetitive behaviors and stereotyped interests (American Psychiatric Association 2013). There is no single assessment that clinicians use to diagnose ASD; rather decisions are based on information accumulated through a number of sources including parent interviews, developmental history, standardized assessments of cognitive, communication, adaptive, and social skills, and direct observation. Another factor that increases susceptibility to pseudoscientific information relates to the

heterogeneous presentation of ASD characteristics. As an example, deficits in social communication range from a complete absence of spoken ability to fluent speech (Tager-Flusberg et al. 2005). Some individuals with ASD demonstrate a lack of interest, awareness, and even avoidance of social interactions, while others are highly motivated by and seek social interaction but do so in socially inappropriate or awkward ways (Wing 1988). This heterogeneity necessitates that treatment or instruction be highly individualized based on the individuals' skills and areas of need. The educational programming for one individual with ASD will differ from his peer with ASD. There is, therefore, no single approach to treating ASD.

The lack of a definitive, universal answer regarding the cause, assessment technique, and treatment of ASD leads to perceived evidence gaps which are being filled with misinformation and ineffective interventions (Smith and MacDonald 2017). Pseudoscientific beliefs are commonly accepted because they play into the innate human desire to create order, and meaning, from information and experiences encountered. Individuals will attribute goals to events and perceive goal directedness in random noise, spot patterns and correlations in the environment, and overdetect meaning in vague or meaningless statements (Boudry et al. 2015). This, coupled with a weak understanding of the nature of science, aids in the spread of pseudoscientific practices. Many pseudoscientific practices gain popularity because consumers erroneously believe that they are backed by scientific evidence (Losh and Nzekwe 2011). In the case of facilitated communication, one study reported that 100% of undergraduate and 83% of graduate students studying speech pathology believed that FC was supported by scientific research (Ganz et al. 2018).

Role of media. Public awareness about ASD has increased over the past decade in large part due to campaign efforts such as the Center for Disease Control's Learn the Signs Campaign, Autism Speaks, and First Signs (<http://firstsigns.org/>) organizations. Media has supported these efforts by drawing attention to various fundraisers

such as the annual "Night of Too Many Stars," hosted by HBO (HBO, 2008 to present) and document series such as a ten-part series on autism featured on the Today Show in February 2005 (The Today Show 2005). Public search data on the Google search engine peak yearly in April during autism awareness month (DeVilbiss and Lee 2014), an indication that public interest and investigation of the condition coincide with the active push for awareness.

Mass media allows for rapid dissemination to a broad consumer audience. It plays an integral role in improving public awareness of ASD, facilitating early screening, and improving general awareness and advocacy for individuals with ASD while also having a notable influence on the spread of pseudoscientific beliefs and practices. Consumers' openness to media and their media preferences significantly relate with their acceptance of pseudoscientific beliefs (Losh and Nzekwe 2011). Pseudoscientific ASD practices are disproportionately represented in mass media publications. More than 75% of treatments mentioned in print media lack scientific support, while stories on the scientifically validated approach, applied behavior analysis, steadily decreased over the past decade. Many of the stories disseminated through media platforms feature anecdotal or personal stories that elicit an emotional response from readers. Accordingly, articles focused on pseudoscientific practices elicited greater positive comments compared to those presenting on evidence-based practices (Schreck et al. 2013). Consumers who rely upon mass media as their primary source of information are likely to encounter repeated messaging from a restricted range of perspectives.

Consumers' perceptions of ASD treatments.

A growing body of literature has focused on understanding knowledge that results from reading printed texts about autism and its treatments. Fleury and colleagues conducted a series of survey studies to evaluate perceptions of ASD treatments based on evidentiary status among different constituent groups, specifically members of the general public (Fleury et al. 2019), parents of children with ASD (Fleury & Chaxiong, under review), and special education teachers (Fleury

& Kemper, under review). In each study, participants were instructed to read four descriptions of pseudoscientific ASD treatments (i.e., chelation, pressure/weighted vests, brushing techniques, gluten-free casein-free diets) and evidence-based practices (i.e., Picture Exchange Communication System, discrete trial training, self-management, social narratives). The credibility of the source providing information about the treatments varied in the text (high vs. low credibility). The researchers created two versions of the survey to experimentally manipulate the credibility of the source providing information of the practice. For example, survey 1 consisted of a professor (high credibility) providing information about discrete trial training. The same information about discrete trial training was presented in survey 2 but from a website blog (low credibility). After reading each description, participants answered questions regarding their familiarity with the practice, the extent to which they accepted or approved of the practice, and the likelihood they would use or recommend the practice.

The extent to which participants were familiar with ASD practices differed across groups. The general public and parents of children with ASD were more familiar with pseudoscientific treatments compared to evidence-based ASD practices. The inverse was found for the special education teacher population. Special education teachers were more familiar with evidence-based practices compared to pseudoscientific treatments. After reading descriptions of different treatment options, however, participants representing all constituent groups provided higher approval ratings of evidence-based practices compared to pseudoscientific treatments. The participants did not differentiate between high-credibility and low-credibility sources. That is, information about a treatment given by a low-credibility source was not perceived differently from that provided by a high-credibility source. In a subsequent study, Fleury et al. (2019) examined the influence of direct instructions that made the credibility of the source that provided the information more salient. Specifically, the researchers asked participants to pay attention to source credibility as they read the texts. The

results showed that while the high-credibility condition continued to be effective, the low-credibility condition resulted in lower scores. These findings suggest that readers will attend to the credibility of the source when instructed, but do not naturally engage in sourcing under normal reading conditions.

Future Directions

Information posted on the Internet is not regulated for scientific accuracy. While mainstream media outlets may preserve their accountability via corrections and/or retractions, no such mechanisms for correcting the spread of misinformation exist within social media (Eckberg et al. 2018). This means that consumers can readily access information that reflects and reinforces their own interests regardless of empirical soundness (Losh and Nzekwe 2011). Confirmation bias may then lead individuals on social media to seek out and accept information that supports their personal beliefs and are likely to retain faulty beliefs even in the face of conflicting evidence. Individual stories are able to go viral with the help of social media (regardless of source credibility), which has led to the rapid spread of misinformation in the modern world. Compounding this issue is that audiences that are likely to use social media, students from middle school through college, lack the necessary skills for evaluating the accuracy of online claims (Eckberg et al. 2018). The following are specific areas that professionals can use to support consumers in thinking critically about ASD treatment information they encounter through popular media.

Attend to source credibility. Source credibility – how believable a source of information is perceived to be – plays a particularly important role when individuals are confronted with either new or discrepant information (Braasch et al. 2012). Being able to distinguish between credible and noncredible sources has important implications for individuals' comprehension of the information they encounter, especially when faced with making decisions about which texts to read in order to learn about a new subject (Strømsø

et al. 2010). Evaluating source credibility, also known as “sourcing,” is not a natural process for readers, particularly novices (Britt and Aglinksi 2002; Goldman et al. 2012; Strømsø et al. 2010). Evidence suggests that readers do not routinely attend to the credibility of characters in narratives unless they are being instructed to do so (Van Boekel et al. 2017); however, explicitly instructing consumers to attend to the source providing the information does influence their evaluation of treatments in the intended direction with information from noncredible sources being viewed less favorably than treatment descriptions from credible sources (Fleury et al. 2019). Consumers should verify the effectiveness of the promoted treatment in question with credible sources including current special education textbooks, special education technical assistance centers, and reputable nonprofit organizations such as the National Professional Development Center on Autism Spectrum Disorder, National Standards Project, the Association for Science in Autism Treatment, and the Organization for Autism Research (Travers 2017). The website links for the nonprofit organizations can be found in the See Also section at the conclusion of this entry.

Address deficits in background knowledge.

Teachers are a particularly influential population in the spread of information as they are commonly a trusted source for families, particularly for children receiving special education services (Adams and Christenson 1998). The concept of EBPs is central to the provision of special education services. The teaching licensure structure varies across states with many states mandate specific endorsements or licenses specifically for teachers who educate students with ASD. These regulations have been enacted to better prepare educators to provide effective, evidence-based instruction for their students with ASD. The extent to which these preservice teacher preparation changes will have on student outcomes, however, is yet to be established.

Engage in the conversation. The general public is susceptible to pseudoscience, particularly those who use mass media as their primary source of information. Pseudoscientific beliefs and treatments are frequently disseminated through

different media outlets such as movies, news publications, and the Internet, while the evidence discrediting them is published by researchers in journals whose primary audience is other researchers. This leaves consumers without access to scientific evidence, which may leave them unaware that it even exists (Ganz et al. 2018). This points to a pressing need for researchers to disseminate their work to broader public audiences. Researchers should be encouraged and supported in publishing their work in accessible language in outlets commonly used by broader public audiences.

Optimize public awareness campaign efforts. Take public awareness campaigns to the next level by tailoring professional development programs to reach a broader audience. The 4C framework (Betsch et al. 2015) stresses that messaging content should differ depending on consumers’ level, and type, of hesitancy toward science. The model was originally developed to explain vaccination hesitancy but may have applications for attitudes toward pseudoscientific ASD treatments. Consumers are classified as belonging to different psychological profiles: complacency, convenience, confidence, and calculation. Messaging for changing attitudes differs across profiles. A figure in which the motivational profiles and outreach strategies can be found in Fig. 2. The content of messaging could contain a combination of strategies including the following: emphasize the importance of EBP for individuals with ASD, warn about the dangers of pseudoscientific practices, debunk misconceptions, make additional training available and accessible to different stakeholder audiences (i.e., general public, caregivers, educators), and incentivize the use of EBPs.

Conclusion. Public awareness campaign efforts and mass media platforms play a significant role in increasing public awareness and interest in ASD. The field has benefited in several ways from increased public awareness including, but not limited to, improved conversations between parents and health-care professionals leading to earlier detection, increased funding for autism research, and greater understanding of the needs of this population. The field has also experienced

Motivation Profile	Strategies							
	Raise perceived risk of unsupported treatment	Stress social benefit of EBPs	Stress that EBPs are the norm in professional communities	Strengthen positive attitudes of EBPs	Change structure to facilitate EBP uptake	Strengthen self-control and implementation	Debunk myths	Incentivize EBP use
Complacency Complacent people passively omit science, rather than actively decide against it. They perceive risks associates with pseudoscientific treatments to be low and demonstrate low levels of knowledge and awareness.	✓	✓	✓	✓				
Convenience Convenience people agree that science is important but other issues are of greater importance. Implementation of EBPs is blocked by structural barriers (i.e., difficult access, costs)				✓	✓	✓		
Confidence Trust in the effectiveness of pseudoscientific treatments, the system that delivers it, and motivation of influencers who decide on its necessity							✓	
Calculation Engage in extensive information search for pros and cons of selected treatment. No pre-conceived attitudes, but instead base decisions on utility maximization	✓	✓					✓	✓

Public Perception of Autism Treatments: Science Versus Pseudoscience in the Age of Mass Media, Fig. 2 Strategies for tailoring outreach efforts based on motivation profiles. Note: The table gives suggestions regarding which strategy can address potential determinants of pseudoscience adoption based on non-vaccination

work by Betsch et al. (2015). This information is presented for theoretical purposes. It has not been tested whether these interventions are especially suitable for the suggested types of pseudoscience adopters. Future research should address this question

growth in the quality and quantity of ASD research, which has yielded a body of EBPs that have ample scientific evidence to support their effectiveness in improving outcomes for individuals with ASD. Despite the existence of EBPs, autism remains a “fad magnet” attracting many consumers to entertain pseudoscientific treatments that either lack ample empirical evidence or have empirical evidence that document a lack of effectiveness. Pseudoscientific beliefs thrive when individuals within a society are willing to both accept and transmit them. Much research has been dedicated to studying the factors that influence people’s acceptance of pseudoscientific beliefs; however, far fewer resources have been dedicated to understanding the willingness of individuals to transmit these beliefs to one another (Mercier et al. 2018). Solely focusing on EBPs is an insufficient tactic to counter the impact of pseudoscience (Vyse 2016).

Instead, consumers who adhere to an evidence-based model for intervention must also be prepared to detect and avoid using unproven and pseudoscientific strategies (Travers 2017). This is an area of much needed research, with important implications for the quality of services required to promote optimal outcomes for individuals with ASD.

³The School at Springbrook, Oneonta, NY, USA

Definition

Punishment is defined as a contingency that results in a decrease in the future rate of a response. The contingent stimuli or events used are referred to as punishers. Punishers fall within two categories, unconditioned or conditioned. *Unconditioned* punishers are stimuli that are effective in reducing behavior without having been previously paired with any other punisher. Examples of such would include electric shock or time-out from positive reinforcement. *Conditioned* punishers are stimuli that, in the past, have been paired with previously established punishers, gain their “punitive power” from such pairings, and, as a result, demonstrate a reductive effect on behavior they follow. Examples would include loss of money (i.e., fining) and reprimands.

There are two different types of punishment procedures, Type I and Type II. Positive punishment (Type I) is the presentation of a stimulus (presumed to be aversive or unpleasant) following a behavior that decreases its future probability of occurrence. For example, if a child bites other children, the parent could deliver a stern reprimand after each biting episode. If the child viewed the reprimand as unpleasant or aversive, then in the future, the child would bite less often. Negative punishment (Type II) is the removal of a stimulus contingent upon a target behavior that reduces its future frequency of occurrence. Examples of negative punishment techniques include time-out from positive reinforcement (loss of

access to reinforcement for certain amount of time), planned ignoring (loss of attention), and response cost (loss of earned reinforcement). For example, time-out from positive reinforcement could be used with the child biting his peers. In this case, the parent could place the child in a chair for a set time period (e.g., 3 min) and access to preferred items prevented. The child would learn that biting leads to loss of access to social and tangible rewards. Future occurrences of biting should decrease.

Historical Background

Punishment has been used over the past several decades as an intervention for behavior deemed inappropriate. It is a technique used in behavior modification based on operant behavior/conditioning principles developed by B.F. Skinner in the 1950s. Operant behavior is any behavior whose future frequency is influenced by its consequences; the fundamental description of the influences on operant behavior is known as the three-term contingency. The three-term contingency consists of the discriminative stimulus (antecedent or environmental cue), operant response (specific behavior), and the consequence (action following the response). For example, a student is sitting in class during school. The teacher asks a question (discriminative stimulus), and immediately the student yells out the answer without raising his hand (operant response). The teacher then verbally reprimands the student for shouting out the answer and not raising his hands (consequence). If the reprimand functions as a punisher, then in the future, the student is less likely to yell out without raising his hand. Over time, the student’s behavior (not raising hand and shouting the answer) would be influenced by its past history of consequences (being verbally reprimanded). It is important to recognize that all operant behavior is influenced by the consequences that immediately follow it. Punishment is a consequence that leads to a reduction in rates of behavior.

Historically, some of the earliest research in this area was conducted in laboratory settings using animals such as rats or pigeons as subjects. Skinner and other researchers used different forms of punishment to influence the occurrence of the animal's behavior. For example, researchers exposed rats to brief electrical shocks contingent upon lever pressing; lever pressing reduced in rate. The earliest studies examined various components of punishment such as the intensity, immediacy, and schedule. Numerous experiments have shown the effectiveness of punishment in decreasing behaviors. This basic research led to the discovery that human behavior was influenced via the same mechanisms.

These earliest studies provided the foundation for further research on punishment with different clinical populations. Beginning in the late 1950s and early 1960s, researchers began using punishment with individuals with autism and other developmental disorders. Many of these individuals displayed a variety of challenging behaviors, such as physical aggression, self-injurious behavior (hitting, kicking, biting self), noncompliance, property destruction, sexual assault, pica (ingesting nonedible items), and stereotypy (repetitive behaviors – rocking, hand flapping, grinding teeth, etc.). Practitioners in schools were responsible for managing these behaviors in order to ensure the safety of individuals, in addition to providing an adequate education. Initially, the goal in many of these situations was to control the individual's behavior and immediately reduce the occurrence of the problematic behavior. A quick reduction in the targeted behavior was often necessary and desired due to the potential for injury if left untreated. Research, in both laboratory and applied settings, showed that punishment provided an immediate suppression of challenging behavior. Providers used a variety of punishment techniques to achieve these reductions.

In the 1970s, ethical concerns about the use of punishment began to surface. Although the research clearly showed that punishment could terminate or reduce targeted behaviors, there often were abuses of its use. Reports of staff and other providers abusing individuals with

developmental disabilities were made public. One of the earliest scandals was in 1971 at a residential facility for persons with developmental disabilities. Individuals were subjected to punishments without consent or supervision. Many were placed in seclusion for long hours, deprived of food, physically restrained, and subjected to cruel and inhumane treatments. This scandal led to the creation of a Blue Ribbon Panel that advocated for more stringent rules regarding the treatment of individuals with developmental disabilities. The concerns about the unethical and illegal use of punishment led to legislation at both the state and federal levels to ensure that future abuses would not occur. This resulted in a marked decrease in the study of punishment and the types of punishers examined. Additionally, the number of studies using potentially harmful aversive stimuli (electric shock, restraint, etc.) decreased as well. There became a greater awareness and need to find safer, more acceptable, and effective interventions. With the passing of the Individual with Disabilities Education Act in 1990, the federal government provided guidelines that caregivers perform functional behavior assessments and rely on more positive practices. The technology of functional assessment became more widespread and focused on the cause of the challenging behavior. By identifying the maintaining cause, caregivers concentrated on interventions directed at the function and relied less on punishment. This approach differed considerably from the goal of previous research on punishment, which was to control the behavior, rather than study the reasons for the challenging behavior occurring. Punishment was still explored, but there were far more stringent ethical guidelines regarding its use.

Punishment has continued to be studied, although the focus of this research has changed. Many of the punishment studies in recent years have used relatively mild aversive stimuli that dramatically reduced the potential for physical or emotional harm. Oftentimes, these studies have paired mild aversive stimuli with reinforcement or some other form of positive strategies. Typically, researchers and practitioners have used punishment as a last resort, and more specifically,

punishment has, in fact, become the default technology that is only recommended to be used when all other interventions have failed. The use of punishment has been highly regulated in both federal and state legislation, with many agencies providing oversight of its use. The general template describes three or more levels of approved aversive stimuli that can be used with varying levels of consent. For example, procedures such as verbal reprimands, response cost, and planned ignoring tend to be much lower level (and thus, more acceptable requiring less levels of consent) of aversive stimuli when compared to over-correction, noxious stimuli (foul smells, water mist, shocks, etc.). Most often, the less aversive stimuli are used. Only in special cases when people are putting themselves or others in significant danger are the more aversive stimuli seriously considered.

Current Knowledge

Behavioral researchers have used a wide range of aversive stimuli as Type I punishment to decrease problem behaviors in students with autism. It is important to recognize that there are drastic differences in the qualitative properties of the aversive stimuli that have been used in the research. These range from relatively mild to severely aversive stimuli. Mildly aversive stimuli include reprimands and response blocking. The potential risk of either physical or psychological harm from these mildly aversive stimuli is considered minimal. In contrast, there is a much greater risk for harm to the individual when more severely aversive stimuli are used, such as physical or mechanical restraint, ammonia capsules, loud noises, air blasts, noxious tastes (lemon juice), facial mist, and contingent electric shocks. Studies have shown that both the mild and more severe aversive stimuli can function as successful punishers to reduce a wide range of challenging behavior.

Type II (negative) punishment involves the removal or loss of a stimulus contingent upon a response that leads to a reduction of that response. An example of negative punishment often used is

“planned ignoring.” The general assumption is that attention is a positive reinforcer for most individuals (however, best practice would require a confirmation of this hypothesis for each individual). Planned ignoring, then, is a punishment procedure in which attention is purposefully denied or removed contingent upon the targeted undesirable behavior. Planned ignoring could include the withholding of social reinforcers including attention, verbal interaction, and physical contact for a brief period of time. Another example of negative punishment is called “response cost.” This is a form of punishment where a specific amount of reinforcement previously earned by the individual is lost or removed contingent upon problematic behavior. This loss of reinforcement results in a decreased probability of the future frequency of the behavior. This procedure includes “fines” or loss of money, tokens, and time with preferred activities contingent upon the target behavior.

There is individual variation with regard to what functions as effective punishment. Some people will find particular stimuli or consequences punitive, while other people will not. Just as individuals vary in terms of what functions as positive reinforcement for them, so it is with punishment. Knowledge of what is and is not aversive or punitive to an individual is essential in determining how and what type of punishment is to be applied.

Once a consequence has been determined to be an effective punisher, there are a number of variables that must be taken into account in order to assure that the most effective and least restrictive procedure is being used. One factor that must be considered is the immediacy of the application of the punisher. The quicker (in time) the punishment follows the occurrence of the undesired behavior, the more effective the punisher will be in reducing future rates of that behavior. For example, a punisher applied within a few seconds of the occurrence of the target behavior should result in quicker and greater progress than delivering the punisher 1 min after the target behavior occurred. Another important factor that will influence the effectiveness of a punisher is its intensity or magnitude (i.e., how much of the punisher is applied). There is a potential danger in applying a

punisher at a low intensity. “Habituation” occurs when the punishing consequence loses its reductive effect due to its application at a low intensity. When using punishment, it is better to use a higher intensity of a punisher to assure that the stimulus will achieve the reductive effect. For example, a student misbehaves in the classroom and the teacher uses the punishment of sitting at desk being quiet with head down. A 5-s duration would be considered potentially less effective than 3 min. A third important factor to consider procedurally is the schedule with which the punisher is applied. Schedule refers to how often and when a punishment is to be used. The typical procedure is to implement the punishment contingent upon each occurrence of the targeted problem behavior. This “continuous” schedule of punishment is considered to provide the most suppressive effect. However, another option is for an “intermittent” schedule of punishment, in which the person applying the contingency does not punish each target response, but rather punishes on a fixed or random schedule (e.g., every third target response). A denser schedule is more effective in rapidly reducing a problem behavior; however, a variable schedule can be used should the continuous application of the consequence require too much time or resources to effectively implement. This schedule of intermittent punishment is not recommended as the effects may take longer to show, and it is not always true that a variable schedule is effective.

Another issue related to the implementation of a punishment procedure focuses on the simultaneous use of reinforcement strategies. A punishment procedure should always be implemented with a positive reinforcement procedure targeting the increase of incompatible or appropriate behavior that will replace the target problem. For example, if a student is hitting herself in the head to gain the attention of a teacher (assuming a level of severity that requires a punishment procedure), a treatment may be put into place that would punish this behavior while simultaneously teaching the student how to request attention appropriately and reinforcing this new behavior. In addition to the reinforcement for the replacement behavior, it is important that there

is an attempt to remove all reinforcement that is being received for the problem behavior that is being punished. Another and a more recent advance in the field is to conduct a punishment assessment to determine the effectiveness of the treatment prior to its application. This requires a clinician, usually in a controlled “test” environment, to expose an individual to a variety of potential punishers to see which has the most suppressive effect.

There are two components that are essential and required before attempting to implement any punishment procedure. First, there should be a definitive plan that describes all of the components of the punishment procedure. The plan should clearly define the behavior that is targeted for punishment, what the punisher is and its intensity, how often it is or is not to be applied, and a standard by which progress will be assessed, including conditions under which the procedure will be removed for health and safety. These details should be scripted clearly so that the training of staff is most efficient, and continued monitoring of the staff employing this procedure can be done most efficiently. Secondly, prior to the application of any punishment procedure, the service provider must gain parental consent. It is recommended that the parents be exposed to the punishment procedure so that they can experience what their child will be experiencing.

Finally, current best practice dictates that the implementer of a punishment procedure take regular data (i.e., per use, daily, etc.) on both the use of punishment and the rate of the undesired behavior both before (i.e., baseline or preintervention) and during the application of the punishment program. With the inclusion of frequent collection and regular review of the data, it is possible to assure clinicians will not only know if their treatment is effective, but, more importantly, they will know when it is not. This is important to discern, since it may be unethical to continue a punishment program if it is not reducing the targeted behavior. If the treatment team confirms, through data review, that the targeted undesired behavior is failing to reduce, the team will likely stop the punishment so that it is not being inappropriately applied.

Before implementing punishment procedures, one must be aware of its potential side effects. The first and most likely is a possible negative reaction, either emotionally or physically, from the individual being punished. In some cases, the use of a punisher could elicit reactions such as crying, avoiding the person who delivers the punishment, or aggressing toward that person. Other possible side effects are that the individual could begin to exhibit escape and avoidant behavior. This could be demonstrated by the individual refusing to do work, lying, cheating, and staying away from the person(s) who administer the punishment or the environments in which the punishment was delivered. An additional side effect of punishment is termed “behavioral contrast.” This means that a behavior punished and suppressed in one context could increase in rate in a different context in which that same behavior is *not* punished. For example, if a particular response is punished in school, but not at home, then there could be an increase in the unwanted response in the home. In addition to the possibility that there may be increases in the behavior under different conditions, there is also the chance that the use of punishment may in fact serve as a model for the punished child for how to deal with undesired behavior in the future. For example, a child on whom punishment was used could be more likely to use punishment in the future, as that was the type of discipline that was used with the child. Although this is not always true, it is possible that spanking a child could result in teaching that individual aggressive behavior, regardless of the intention of the original intervention, is tolerated and a way to deal with unwanted behavior. Finally, the act of punishing a behavior has the potential to reinforce the individual providing the punishment. Since punishment is often effective in obtaining an immediate effect of stopping the punished behavior, the person using the punishment will see an immediate effect, which could reinforce the use of this approach. If one loudly reprimands a child because she is spilling something and the spilling immediately stops, it is likely that punishment will be used again in the future. To prevent this from occurring, it is important that a strict schedule and set of rules be

determined on a case by case basis, carefully describing when, how long, and how often a punisher will be applied to assure that an individual is not overexposed or harmed by the unnecessary application of a punisher.

Future Directions

While previous research has shown that punishment has been successful in reducing problems behaviors, there remain several different areas that require further exploration. One relates to the magnitude of punishment. The magnitude of a punisher refers to size or intensity of the aversive stimulus used contingent upon behavior. For example, if parents were to place their child in a time-out chair for 10 min, then the magnitude of the punishment would be 10 min. These results could be compared to the effects that 15 min have on the rate of the child’s behavior. This research would be significant to the applied field because it would provide practitioners the ability to identify and use the least intense or smallest magnitude of aversive stimuli that is effective in reducing the behavior. With this information, practitioners could implement an aversive stimulus that was just “strong enough” to decrease the behavior. This would help minimize the risk to individuals in that only the necessary magnitude of the stimulus that was needed to reduce behavior would be used.

The schedule of punishment is another area that needs further study. Research in this area has shown that punishment is most effective when it is implemented after every occurrence of the targeted behavior. Oftentimes, implementing the punisher after every occurrence can become cumbersome and difficult for practitioners. The goal of most interventions including reinforcement and punishment is to ultimately fade or gradually remove the intervention. A select number of studies in the late 1970s examined this topic and showed that an intermittent schedule of punishment may be sufficient in some circumstances to reduce problem behavior to a socially acceptable level. However, further research is needed to provide a better understanding of the conditions

under which an intermittent schedule could be effective. This knowledge would ultimately help practitioners completely remove the intervention over time.

The identification of stimuli that will function as an effective punisher is another area in need of investigation. There are only a few studies in the literature that describe procedures to systematically identify stimuli that would potentially serve as effective punishers. These punisher assessments typically involve presenting various potentially aversive stimuli and measuring levels of compliance, resistance, and negative affect. The development of these assessments may give practitioners a way to determine the most effective punisher for an individual, and allow for quicker identification of possibly aversive stimuli that could then be implemented, should the need arise.

A related area of research would be to investigate if more mild and socially acceptable stimuli could function as effective punishers. Punishment does not necessarily need to involve physically painful or noxious stimuli. Research could be conducted to identify if daily activities that an individual found unpleasant (or not preferred), but not physically uncomfortable, could serve as a punisher. For example, if a child did not enjoy coloring and found it aversive, then would coloring serve as an effective punisher when implemented contingent upon a targeted behavior? If these activities were effective, then this may allow practitioners to use more socially acceptable and presumably safer stimuli as punishers should caregivers need to resort to procedures more intrusive than reinforcement.

Punishment is a complex process. The majority of research regarding punishment was conducted many years ago in laboratory settings. Such research allowed for the tight control of numerous variables that is nearly impossible to achieve in applied real-life situations. Clinicians have recognized a need to examine the practical applications of punishment in field settings and with populations such as persons with autism. It is important to determine how effective punishment techniques can be used in educational settings where environmental variables may not be as clear or under as much control. Although

legislation does afford needed protection of persons with whom punishment may be used, the abolishment of punishment may not be the answer for safe-guarding individuals receiving behavior support. One key solution to preventing abuse through improper punishment is to understand the conditions and guidelines under which punishment has been proven both safe and effective. These standards have been researched and are well understood, and provide a guide by which punishment can be an appropriate and useful treatment option for those in need of behavior modification.

Punishment should be studied further and its components understood to allow for a richer knowledge of the factors that influence its effectiveness, and the conditions under which the clinical use of punishment is warranted. With this information, clinicians and providers will have the knowledge to use these interventions most effectively. An increased understanding will help assure that individuals with autism receive the safest and most effective treatment possible. It is important that researchers continue to explore the use of punishment in an effort to provide practitioners with the most effective interventions for their clinical use.

Purdue Pegboard

Pamela E. Ventola
Yale Child Study Center, School of Medicine,
Yale University, New Haven, CT, USA

Description

The Purdue Pegboard test measures two types of dexterity: one involving finger dexterity and the other involving the movement of arms, hands, and fingers. The test itself is small, can be administered quickly (about 10 min including all necessary instructions and modeling), and is relatively simple to administer and perform, making it a useful instrument for a wide variety of populations and clinical and industrial settings.

The test consists of a pegboard with 2 rows of 24 holes and 4 cups at the top of the board for storage of the pegs. The test is comprised of four elements: dominant hand, nondominant hand, both hands, and assembly. For the dominant hand portion, the subject inserts small pegs into holes on the board using only the dominant hand. The examiner instructs the subject to only pick up one peg at a time. The examiner then times the subject for 30 s and counts the number of inserted pegs. For the nondominant hand aspect, the procedure is the same, but the subject is asked to only use the nondominant hand. Regarding the both hands element, the subject places two pegs simultaneously, one with each hand, in two rows on the pegboard. The subject is told to only pick up one peg at a time with each hand. The examiner times the subject and counts the number of pairs of pegs inserted after 30 s. For assembly, using both hands, the subject assembles sequences of peg, collars, and washers. The examiner instructs the subject to utilize an alternating approach, placing the peg in the hole with the dominant hand while using the nondominant hand to pick up the collar and then, while placing the collar, using the dominant hand again to place the washer. The examiner times the subject for 60 s and records the number of parts placed.

After all three conditions are completed, the examiner compares the raw score (number of pegs or assembly parts) for each element to the normative data in order to derive the subject's standardized scores.

Historical Background

The Purdue Pegboard test was first developed in 1948 by Joseph Tiffin, Ph.D., industrial psychologist, of Purdue University. He developed the test as a means of measuring manual dexterity for the purpose of selecting employees for industrial and assembly line jobs. In the seminal paper on the Purdue Pegboard test, Tiffin and Asher (1948) wrote that one of the most important aspects of the test was that it was standardized under conditions in which groups of employees could be tested together; one examiner using a

battery of 10 peg boards could test 50 people an hour, making it an efficient means of measuring the manual dexterity of potential assembly line and factory workers. The initial normative data for the Purdue Pegboard was obtained from thousands of students and employees working a variety of industrial jobs and divided into five groups: college men and women, veterans, and industrial men and women. Tiffin and Asher (1948) also reported on the reliability and validity of the instrument. The test-retest reliability was high. The validity was calculated against industrial job performance, and the validity coefficients varied indicating the importance of determining the validity of the Purdue Pegboard separately for each job its use was being considered.

Since its development in 1948, the Purdue Pegboard test has become one of the preeminent tests of dexterity in clinical, research, and vocational settings. It has been utilized to investigate the relationship between cognitive constructs and motor dexterity as well as to examine the relationship between motor dexterity and pathology. For example, the initial studies on the Purdue Pegboard indicated a significant relationship between intelligence as measured using the Wechsler Adult Intelligence Scale (WAIS) and manual dexterity in individuals with cognitive impairment (Phillips and Holden 1967). Additionally, the Purdue Pegboard test was able to discriminate between individuals with brain injuries and controls, indicating its potential use as a screen for brain injury (Vega 1969). Performance on the Purdue Pegboard test also discriminated between children with reading disabilities and typically developing children (Leslie et al. 1985). Lastly, performance on the Purdue Pegboard test was related to future factory workshop capability in individuals with moderate to severe levels of mental retardation (Presnall 1979). More recently, the Purdue Pegboard test has been used as a measure of motor functioning in a variety of clinical groups, including autism, Tourette's syndrome, schizophrenia, and Parkinson's disorder. Refer to the Clinical Uses section for further information.

Psychometric Data

Normative Data

Tiffin and Asher (1948) collected the initial normative data on college students, veterans, and factory workers. Additional normative data on a variety of populations has also been collected. Gardner and Broman (1979) collected normative data on over 1,300 school-age children. Hamm and Curtis (1980) also reported normative data on 340 adolescent/adult candidates for vocational rehabilitation who were suspected of having a cognitive or physical disability. Wilson et al. (1982) presented normative data on over 20 preschool-age children (2–5 years).

Reliability

The reliability of the Purdue Pegboard test has been widely studied and is generally considered to be adequate to strong. Test-retest reliabilities from the first edition of the Purdue Pegboard manual ranged from 0.60 to 0.71 for one trial and 0.82 to 0.91 for three trials. For the three-trial approach, each subject was administered the conditions three times, and the means of the scores were obtained (Tiffin 1968; Tiffin and Asher 1948). More recently, Buddenberg and Davis (2000) evaluated the test-retest reliability of the Purdue Pegboard with 1 week between administrations. For the one-trial administration, reliabilities ranged from poor to adequate (0.37–0.70) with the highest reliability for the combined score. The reliability was higher with a three-trial administration, with all of the reliability scores being excellent (>0.80).

Validity

Tiffin and Asher (1948) initially reported on the validity of the Purdue Pegboard test based on a compilation of several studies that compared the performance on the test with factory job performance. The validity coefficients ranged drastically from 0.07 to 0.76 depending on the type of job to which performance on the pegboard was compared, indicating that the validity of the Purdue Pegboard should be individually determined based on the job for which its use was being considered.

A study on the intercorrelation of the Purdue Pegboard tests (dominant hand, nondominant hand, both hands, and assembly) found that the peg placement elements were more strongly correlated with each other than with the assembly element. These results led the authors to conclude that the Purdue Pegboard measured two factors: finger dexterity or the “ability to make rapid, skillful, controlled manipulative movements of small objects, where the fingers were primarily involved” and manual dexterity as defined as the “ability to make skillful, controlled arm-hand manipulations of larger objects” (Fleshman and Ellison 1962).

The Purdue Pegboard also has strong discriminative validity, as for example, when using criteria established by Costa et al. (1963), performance on the pegboard discriminated between patients with brain damage and controls with about 90% accuracy, and it was also possible to indicate the laterality or diffuseness of brain damage in about 70% of cases. Costa et al. (1963) criteria are published in the examiners manual.

The Purdue Pegboard also discriminated between typically developing children and children with a wide range of psychological/neurological conditions (Rapin et al. 1966). In this seminal validity study, almost all of the typically developing children achieved scores within the normal range, but just over 20% of the children with brain injury or intellectual disability achieved scores in the normal range. The Purdue Pegboard test was also reported to be sensitive to “non-motor brain damage, including the syndrome of clumsiness, hyperactivity, and visual motor dysfunction.”

Clinical Uses

The Purdue Pegboard was initially designed as an industrial psychological instrument for the purpose of assessing the manual dexterity of factory workers as a means of predicting productivity. Since its inception in 1948, it has been widely used in employment settings but also as a measure of motor functioning in clinical research.

The Purdue Pegboard has been used to measure motor functioning in a wide variety of clinical populations. For example, the Purdue Pegboard has been instrumental in demonstrating the subtle motor impairments associated with individuals with Tourette’s syndrome (TS) and tic disorders, and performance on the Purdue Pegboard has been used to predict outcome in individuals with TS (Bloch et al. 2006). Impaired motor skills in children with attention deficit hyperactivity disorder (ADHD) has also been demonstrated using the Purdue Pegboard test, and performance on the Purdue Pegboard is correlated with attention, more generally, in typically developing individuals (Strenger et al. 2002; Sukhodolsky et al. 2010). Furthermore, children with ASD often have poor motor skills, and this finding has been confirmed in studies using the Purdue Pegboard test (Mandelbaum et al. 2006). Lastly, the Purdue Pegboard test has been used extensively in schizophrenia research to assess motor functioning, as motor deficits are commonly seen in individuals with schizophrenia.

Clinical researchers also have widely used the Purdue Pegboard as a measure of motor functioning in treatment studies. Notably, Aman et al. (2008) used the Purdue Pegboard test as part of a battery to assess the cognitive effects of risperidone in children with ASD. Similarly, the Purdue Pegboard test has been used to measure the cognitive impact of antipsychotic medications in schizophrenia, and it has been utilized as an outcome measure to assess the efficacy of treatments for Parkinson’s disease.

Overall, the Purdue Pegboard was developed to assess dexterity in factory workers, but over its 60-year history, it has proved to be a valuable tool for assessing manual motor dexterity more broadly and has been utilized extensively in clinical research with a wide variety of clinical populations.

Graduate School of Medical Sciences, Nagoya
City University, Aichi, Japan

Definition

Purines and pyrimidines are compositional units of DNA and RNA. They play important role not only for genetic information but also for many metabolic steps as formation of coenzyme and intermediates.

Disorders of purine metabolism such as Lesch-Nyhan syndrome are well known and described elsewhere, but defect of pyrimidine metabolism is known comparatively recently. The final product of purine metabolite in human is uric acid, which is easily detected and measureable, but there is no equivalent compound in pyrimidine metabolism. So, many patients with pyrimidine metabolism defect may be followed as unexplained diseases.

Deficiency of dihydropyrimidine dehydrogenase (DPD) which is the first enzyme of pyrimidine degradation pathway causes increase levels of uracil and thymine in blood and urine. The patients of this deficiency show very wide spectrum of clinical symptoms. Almost half of the patients have convulsion, mental and/or motor retardation and growth retardation, microcephaly,

and dysmorphism, and ocular abnormalities are seen in smaller part. Autism is also observed 18% of the patients with DPD deficiency. Etiology is unknown, but DPD deficiency is one of the related disorders of autism.

Purkinje Cells

Ilanit Gordon
Child Study Center, Yale University, New Haven, CT, USA

Definition

Purkinje cells are large neuronal nerve cells that occupy the middle layer of the cerebellar cortex (also known as the Purkinje layer). These cells were discovered in 1837 by Czech anatomist Jan Evangelista Purkinje who identified and described them. Structurally, Purkinje cells are characterized by a long axon and numerous and intricate dendritic spines branching from the cell soma. Purkinje cells regulate coordinated motor activity by releasing the neurotransmitter GABA (gamma-aminobutyric acid) projecting to deeper cerebellar nuclei and exerting inhibitory influences upon the receiving cells. Purkinje cells have a large deal of control over the refinement of motor activities as they have an essential part

in the cerebellum's role in receiving information from the cerebrum and planning coordinated activity in response. Damage to Purkinje cells can result in certain neurological diseases. The loss of Purkinje cells has been observed in children with autism.

Putamen

Sarah Shultz
Department of Psychology, Yale University, New Haven, CT, USA

Structure

The putamen is a subcortical structure situated at the base of the forebrain between the lateral medullary lamina of the globus pallidus and the external capsule. The putamen, caudate nucleus, globus pallidus, and amygdala form the basal ganglia. The rostral portion of the putamen is continuous with the caudate nucleus, forming the dorsal striatum.

Function

The putamen and other structures of the basal ganglia play an important role in many motor and cognitive functions, such as initiating, regulating, and monitoring movements. The putamen also plays a role in learning and memory, specifically in the acquisition of stimulus–response associations over time.

Pathophysiology

Putamen dysfunction is thought to be associated with repetitive behaviors in individuals with ASD (Hollander et al. 2005; Estes et al. 2011). While repetitive behaviors are reportedly correlated with basal ganglia dysfunction, studies of putamen volume in ASD report no difference between typically-developing individuals and individuals with ASD (Hardan et al. 2003; Sears et al. 1999; Langen et al. 2007; Estes et al. 2011).

Pyramidal System

Martha D. Kaiser and Randi Bennett
Child Neuroscience Laboratory, Yale Child Study Center, New Haven, CT, USA

Definition

Pyramidal cells are neurons with a pyramid-shaped cell body, one large apical dendrite, and several smaller dendrites at their base. They are mainly located in the gray matter of the cerebral cortex, corticospinal tract, and the hippocampus. Their axons may have local collaterals, but they are also able to project outside their cortical region. The development of normal motor control is dependent upon the development of connections between the axons of the pyramidal cells in the corticospinal tract and the spinal cord.

Qatar and Autism

Fouad A. W. Alshaban
Neurological Disorders Research Center, Qatar
Biomedical Research Institute, Hamad Bin
Khalifa University, Doha, Qatar

Historical Background

Similar to most countries within the region, Autism Spectrum Disorder (ASD) awareness and programming in Qatar have been changing rapidly throughout the past years. Despite ASD being recognized by medical professionals and cases are detected at an estimated similar rate to international trends, ASD was not documented as a separate disability category in Qatar's national statistics until 2012 (Ministry of Development Planning and Statistics 2013). Nonetheless, the country's leadership has shown special interest in ASD as there is a recognition of its growing prevalence and the need to provide services for the affected individuals and their families. Hence, on April 2, 2008, Qatar officially joined the United Nations in announcing April 2nd as the world's "Autism Awareness Day," an event which was proposed to the UN by Her Highness Sheikha Moza Bint Nasser (United Nations Meetings Coverage and Press Releases 2008). Yet, ASD and general special needs services were operational years before this event. In fact, the history of ASD services and policy developments in

Qatar are all linked back to initiatives launched by HH Sheikha Moza Bint Nasser.

The first unit designated to serve children, adults, and elderly with special needs was opened in 1982 at the country's main healthcare provider; Hamad Medical Corporation (HMC) – Rumailah Hospital. However, the buildings and organizational structure changed rapidly until 2012, when the Child Development Center was opened to provide services for children with different disabilities including ASD. Children with ASD (3–6 years) started receiving early intervention by the multidisciplinary team of professionals within the Autism Program; assessment, diagnosis, and early intervention.

In 1999, a significant development in Qatar for ASD service provision was the establishment of the Shafallah Center for Children with Disabilities (formerly known as the Shafallah Center for Children with Special Needs). It was established under the guidance of HH Sheikha Moza Bint Nasser to meet the increasing demands for services to children with special needs. The Shafallah Center is currently servicing a large number of individuals with ASD in the country. Most recently, in 2016, Qatar Foundation opened the "Renad Academy" to join in the venture of providing services to children with ASD and their families. Many private centers' programs have also been developed during these years to meet the increasing demands. These centers are all licensed by the Ministry of Public Health and the Ministry of Education.

Programs to assist in transitioning children with ASD into mainstream education were not functional until the Additional Educational Support Needs (AESN) policy was passed by the Ministry of Education (formerly known as the Supreme Education Council) in June of 2009 (Supreme Education Council 2009). To support and enhance the process of academic and social inclusion, the Ministry of Education also established the Evaluation Institute in 2009. This institute started offering individual student evaluations to serve the needs of diverse learners, including children with ASD who are attending mainstream schools. To further support this process of inclusion, Qatar Assistive Technology Center (known as “MADA”), a nonprofit organization was established in 2010 by the Ministry of Information and Communication Technology to provide assistive technology support to children, adults, and families of individuals with special needs.

“Best Buddies – Qatar chapter” was founded in 2007 under the umbrella of the Shafallah center. It is a nonprofit organization dedicated to enhancing the lives of individuals with intellectual disabilities by providing opportunities for one-to-one friendships and integrated employment. This organization is another example of the inclusion movement and change in societal attitudes and perspectives towards individuals with disabilities.

Legal Issues, Mandates for Service

In Qatar, Autism was not reported as a separate disability category until 2012, as it used to be reported within the intellectual disability classification (Ministry of Development Planning and Statistics 2013). In 2004, the first law that regulates the rights of persons with disabilities was issued (Law No. 2) (Qatar Legal Portal 2004). The 14 articles within this law reinforced the social view of disabilities and paved the way for the succeeding mandates in the years to follow. Rights of persons with disabilities are also included in the sustainable development plan, which is part of Qatar National Vision 2030 (General Secretariat for Development Planning 2008).

ASD in Qatar has affected families from all ethnic backgrounds and different socioeconomic status; it became a disability that has increasing awareness and concern in Qatar and the region. As mentioned previously, in 2007, Qatar joined the UN member states in marking April 2nd as the world’s “Autism Awareness Day.” This event came in conjunction with increased involvement of Qatari authorities to expand healthcare and social services provision to those affected with ASD. In 2007, the social security act provided monthly benefits to persons with disabilities, which included a monthly cash allowance for domestic help (Committee on the Rights of Persons with Disabilities 2015). In 2008, Qatar ratified the United Nations Convention on the Rights of Persons with Disabilities (UNCRPD) and adopted all the rights contained within this convention by April 2015 (Committee on the Rights of Persons with Disabilities 2015).

On the educational and health care level, the country continues to make more government-funded services available for both nationals (Qataris) and expatriates (other nationalities). This includes evaluation clinics to diagnose and assess children with special needs that come in line with the country’s decision on inclusion of children with disabilities into the public school system, through either full or partial integration.

In terms of ASD specifically, it has been recognized within the health, education, and labor sectors. Thus, individuals with ASD are protected by the local and international laws on the rights of individuals with special needs. Autism remains as a separate category in the mandates of the Ministry of Education, and the support system specified involves individualized planning tailored to each students’ abilities and areas of need. In line with this, a total of 63 of the country’s independent (government-funded) schools include a department for special education and inclusion services for students with ASD and have support staff who have the necessary qualifications to support the student’s learning on a daily basis. Moreover, it has created two new schools for children with autism (Al-Hedaya school)

approximately between ages 5 to 17 years. The purpose of Al-Hedaya school is to prepare as many students through early intervention to be ready for entry into mainstream educational setting; through providing intervention in a physical environment that is similar to a school. Nonetheless, as all individuals with ASD differ in response to early intervention and may not all eventually reach mainstream education system, Al-Hedaya school still fills another gap in early intervention for ASD in Qatar. Lastly, the establishment of Rou'a Assessment, Advice, and Support Center has provided schools with a specialized referral entity for detected cases, as well as for progress monitoring and educational program modifications as found suitable for each individual student with ASD.

At the postsecondary educational level, Qatar University established a center known as the "Inclusion and Special Needs Support Center," to ensure that the proper accommodations are provided based on each student's needs to succeed and fully participate in all aspects of university life.

In 2016, the World Innovation Summit for Health (WISH) issued a report on autism with recommendations for improvement of service provision internationally (Munir et al. 2016). In 2017, the National Autism Plan was launched in collaboration with the World Health Organization (WHO). The working group included stakeholders from around the country. This group was charged with creating a National Autism Plan based on six pillars: awareness; early recognition and screening; diagnosis and assessment; interventions; school services; and transition to adulthood. In 2017, the World Innovation Summit for Education (WISE) developed a report, which reviewed ASD services provision in Qatar and highlighted the areas of need. On June 9, 2019, Qatari stakeholders had a significant presence during a panel discussion at the United Nations Headquarters in New York (11–13 June); Qatar Biomedical Research Institute (QBRI), Shafallah Center, MADA, Hamad Bin Khalifa University Health and Human Technology Department, and Qatar Foundation

for Social Work. The delegation partook in panel discussions held on the sidelines of the 12th session of the Conference of the States Parties to the Convention on the Rights of Persons with Disabilities. The panel discussions were about the role of technology in assisting people with autism in education and the workplace to ensure nondiscrimination and facilitate their full and effective participation.

This brief review of the trends in Qatar's legal recognition and support service provision for ASD demonstrates a continuing strive to improve the lives of individuals affected with ASD.

Overview of Current Treatments and Centers

The diagnostic services usually involve a multidisciplinary team of professionals that includes a developmental pediatrician, child psychiatrist, psychologist, and other relevant specialists. The main diagnostic tools used are the DSM-5 criteria, ADOS-2, and ADI-R, in addition to the use of the main ASD screening tools such as the Red Flags Checklist (RFC) in well-baby clinics which is recommended by the Ministry of Public Health, M-CHAT, SCQ (which has been translated into Arabic language and validated by a research team in Qatar (Aldosari et al. 2019)), and others. ASD diagnostic services are available mainly at Rumailah Hospital, HMC's Behavioral Clinic, Shafallah Center for Children with Disabilities, and Sidra Medical & Research Center.

Intervention services which include:

- Child and family medical and social support services
- Multidisciplinary early intervention services
- Family training and counseling
- Mainstream education inclusion support
- Transition planning; independent living and employment services

These intervention services are offered at a public and private sector basis. The first government-funded and the country's largest center servicing more than 150 individuals with

ASD is the Shafallah Center for Children with Disabilities. Meanwhile, early intervention programs for ASD are mainly offered by Rumailah Hospital as well as some other private centers such as the Child Development Center which provide a comprehensive multidisciplinary early intervention programs that include; behavioral, speech, occupational, and physical therapy, and other relevant services. Recently, Qatar Foundation has joined this venture with the opening of Renad Academy. All of the intervention service centers foster a curriculum based on evidence-based practices. These practices include Applied Behavior Analysis, Pivotal Response Training, Verbal Behavior, Discrete Trial Training, Treatment and Education of Autistic and Communication related handicapped Children (TEACCH), etc.

The Shafallah Center for Children with Disabilities is the only center offering services from early intervention to employment and independent living training. The Ministry of Education also provides curriculums and programs consisting of 2-year preparation and then a 6-year vocational training. It also provides 4 years of vocational qualification training such as “carpentry, book binding, painting, agriculture, and poetry for boys; sewing, embroidery, and home economics for girls” (Ministry of Education 2007). All of the public and private programs offered are conducted by a multidisciplinary team of professionals that require the licensing of the Ministry of Public Health and the Ministry of Education.

The National Autism Plan (2017–2021) includes 44 recommendations to be implemented by 2021. It contains some short-term targets which should be applied within the first year of the plan. It aims at improving the quality of the offered services and continues the development of care, education, and community participation. These initiatives will further enhance the quality of the present services and align all services with Universal Best Practices for ASD intervention programming and education in Qatar. A taskforce created and monitored by the Ministry of Public Health has been delegated to follow up on the implementation of the National Autism Plan.

Overview of Research Directions

Despite minimal publications about ASD in Qatar, it has been increasing in the past few years. To date, ASD research included investigations about: the quality of life of caregivers (Kheir et al. 2012); social robotics for ASD (Qatar University 2016); clinical case reports (Al-Sarraj et al. 2014; Ahram et al. 2017); and an overview of Autism and Applied Behavior Analysis in the GCC (Kelly et al. 2016). Moreover, QBRI published the first paper about clinical characteristics of ASD in Qatar with factors including consanguinity, gender, socioeconomic status, co-morbidities, etc. The study was titled “ASD in Qatar: Profiles and Correlates of a Large Clinical Sample” which described the clinical characteristics of ASD for 171 cases enrolled in Shafallah Center (Alshaban et al. 2017). Most recently, the Autism research team at QBRI concluded a country-wide prevalence study which started in 2013. This research involved the collection of data about all diagnosed cases from 2013 to 2017, as well as screening more than 100 mainstream primary schools in Qatar (both public and private schools). The screening process included using the Arabic translated and validated Social Communication Questionnaire (SCQ) in detecting cases of ASD. Those who scored above the cut-off were invited for assessment to confirm or exclude the ASD diagnosis through using; clinical observation, DSM-5 criteria, and ADOS-2 diagnostic tools. The prevalence rate of ASD in Qatar was estimated at 1.14% (Alshaban et al. 2019), which is consistent with international research findings. Moreover, QBRI conducted a research project in collaboration with Cleveland Clinic (USA), in which the team created and validated the Arabic version of the English stimuli paradigm to be used in eye tracking device. Efforts are being made to incorporate it with the English algorithm software at Cleveland Clinic so that it could be used as one of the early objective screening and diagnostic tools for ASD. This is considered as an ambitious and pioneering project for Qatar and the region.

Furthermore, an Autism Genetic Research Program in Qatar started in 2007 through joining

the Autism Genome Project, an International Consortium for Autism Genetic research. The Shafallah Medical Genetics Center (now part of QBRI) took the lead with more than 160 families participating in that project. QBRI continues to lead the Autism genetic research program together with Sidra Medical & Research Center, in collaboration with other Qatari and International institutions. QBRI scientists will be undertaking another QNRF funded research project titled “Autism Spectrum Disorder; Epigenetics; Environmental exposure; DNA and chromatin; Gene Expression from Clinical samples.” Moreover, the research team also investigated the clinical characteristics of all ASD cases diagnosed through the prevalence project, examining the effect of parental age as a risk factor in ASD prevalence. One of the key findings was that consanguinity was not found to be a significant risk factor for ASD, nor to familial reoccurrence of ASD; nonetheless, it was found to predict the severity of ASD (Alshaban et al. 2019). More notably, the QBRI prevalence study yielded the first national ASD registry, which contains 110 demographic, medical, developmental, and educational variables for all cases diagnosed with ASD. This registry will serve the country’s future ASD research and service planning. Currently, QBRI Autism research team plans to conduct a study about the prevalence of grown-up individuals (13 years and above) with ASD in Qatar and to create an ASD registry for this age group, meanwhile another team from WISH will evaluate service availability and quality of life for those individuals.

Overview of Training

Professional training for individuals working with children with ASD in Qatar occurs at different levels; post-secondary training, ongoing professional training, and training workshops, conferences, and symposiums by both the public and private stakeholders. Regarding postsecondary training, Qatar University’s college of education offers three programs: Bachelor, Diploma, and Master programs in Special Education. The

programs have US accreditation, and the curriculum ensures that graduates leave with knowledge about the best universal practices in ASD intervention. These programs include mandatory supervised field training.

Ongoing training of teachers and specialists is offered by two entities: the Evaluation Institute (known as Ro’a center) and the National Center for Educator Development (NCED) at Qatar University. These institutions provide training workshops as well as ongoing support through field visits to the mainstream schools.

In 2014, QBRI organized ADOS-2 and ADI-R training course for healthcare professionals in association with BeginningwithA Autism Consultancy and Training; a total of 24 professionals from the Shafallah Center, Rumailah Hospital, QBRI, and Al Tamakun school were trained and licensed in administering the ADOS-2 and ADI-R diagnostic tools. In 2017, the same training was organized by QBRI and another 21 professionals from similar service providers were trained and licensed in the aforementioned diagnostic tools.

Lastly, training conferences, symposiums, and workshops take place throughout the year by different organizations and centers. These training events are offered either free of charge, or for a cost accompanied with Professional Development (PD) hours or Continuing Medical Education (CME) hours. The target audience is usually professionals, healthcare providers, and families. Some centers such as the Child Development Center (a private center offering early intervention services for children with ASD and other developmental delays) host an annual training symposium targeting professionals and families. Meanwhile, HMC, Sidra Medical & Research Center, QBRI, and other private centers have training workshops throughout the year, to raise awareness and knowledge about ASD and other related disabilities. For instance, in May 2017, QBRI organized its first Autism symposium which hosted professionals from the gulf countries and the United States, Cleveland Clinic, Oregon Health and Science University, Autism Speaks, etc. The second Autism symposium is currently being planned to be held in April 2020.

Social Policy and Current Controversies

ASD awareness is evidently higher within the Qatari society. With the government's support for outreach events, the impact is noticeable during each annual Autism Awareness Month of April, as more organizations take the initiative, come together to raise awareness, and collaborate to offer different activities for individuals with ASD and their families. Moreover, local nonprofit organizations such as Qatar Autism Families Association (QAFA) and the Qatar Autism Society are examples of social movements that serve as a unified voice of the families' demands and offer ongoing community support. Past and current debates about ASD continue regarding the need for the increase in the provision of diagnostic and intervention services. Nonetheless, the government's efforts continue to expand ASD services provision to accommodate the increasing number of diagnosed cases. Meanwhile, some of the private centers compete to provide quality services at a high cost that some families cannot afford. Debates also revolve around the need for more educators and other specialists to successfully include students with ASD and other disabilities into the mainstream schools. Some families seek to hire a private therapist, tutor, or instructional assistant (shadow teacher) to help in the provision of certain needed services. Support in transitioning an individual with ASD through the education to employment to independent living is a process which has been improving with the existing services offered by the adult training unit in Shafallah Center, Ro'a Center (Evaluation Institute), and the Inclusion and Special Needs Support Center at Qatar University. However, the center at Qatar University is only equipped with staff and resources to serve specific physical and learning disabilities, and ASD is not listed as one of the disabilities that the center can provide services for. Moreover, the adult training unit at Shafallah Center cannot cope with the needed transition services for all ASD cases within Qatar.

Qualitative Versus Quantitative Approaches

Susan A. Mason
Services for Students with Autism Spectrum Disorders, Montgomery County Public Schools,
Silver Spring, MD, USA

Synonyms

Case study; Cause and effect; Correlational; Descriptive research; Ethnography;

Experimental research; Group research; Phenomenology; Pre-, during, and posttest design; Pre-post design; Pre-post-posttest design; Quasi-experimental; Single case; Single-subject design; Within-subject design

Definition

Qualitative approaches refer to research that is both descriptive and systematic. It allows the researcher to examine relationships between activities, situations, and materials (Fraenkel and Wallen 2006 in Gast 2010). It is a systematic approach to studying phenomenon within a particular context (Gast 2010). In qualitative research approaches, the researcher is a participant observer who goes from specific to more general by process of inductive analysis and does not focus on generalization of results. Qualitative methods focus on groups, in-depth interviews, and reviews; they are an inductive process used to formulate theory. Qualitative methods do not rely on statistics or numbers and are less generalizable than quantitative methods. Qualitative research approaches are subjective in nature. Brantliger et al. (2005) in Gast and Ledford (2014) noted, qualitative research is concerned “with understanding qualities or the essential nature within a phenomenon within a particular context (p. 195). “Qualitative research provides “detailed, in-depth descriptions of case phenomena under study” (Gast and Ledford 2014, p. 10).

Quantitative approaches to research are based on formal, objective, and systematic processes in which data are numerically quantified. Another hallmark of quantitative research is replicability. Quantitative approaches are objective, deductive, and based on numeric quantification and generalization of results. Quantitative methods are used to test prespecified concepts, constructs, and hypotheses that make up a theory. Most commonly used quantitative methods include group design research and single-subject (within subject/single case) research designs; the latter is theoretical and based on specific research questions rather than

hypotheses. Both group research designs and single-case designs are more generalizable. In group design, the generalization comes in larger numbers in the sample; in single-subject designs, generalization is accomplished through replication of findings. Quantitative research approaches are objective in nature and rely on replication either in group numbers or by independent researchers as is the case with single case research designs (Gast and Ledford 2014).

Quality of Life for Transition-Age Youth with ASD

Elizabeth E. Biggs
Department of Special Education
University of Illinois, Urbana-Champaign,
Champaign, IL, USA

Definition

Quality of life is a multidimensional and complex concept addressing the health, well-being,

satisfaction, and comfort of individuals (Rapley 2003). In addition to being multidimensional, researchers have identified the importance of both subjective and objective indicators of quality of life. Objective features consist of those that can be measured through observation, such as employment, daily activity patterns, and maladaptive behavior. Subjective features exist in the private thoughts and perspectives of individuals and can be measured through either self-report or proxy report (Cummins 2005). The multidimensional nature of quality of life is difficult, as there is no agreement on which dimensions comprise the concept. For example, in a review of quality of life literature, Felce and Perry (1995) identified five core dimensions of the concept: physical well-being, material well-being, social well-being, emotional well-being, and development and activity. Schalock (2000) proposed a definition that includes eight core dimensions: emotional well-being, interpersonal relationships, material well-being, personal development, self-determination, social inclusion, and rights.

For transition-age youth with autism, quality of life is especially important to consider as many changes and challenges – physical, interpersonal, educational, mental – can emerge during this time period (Biggs and Carter 2016; Clark et al. 2015; Wei et al. 2015). While navigating these transitions can be difficult for anyone, young people with autism may experience even more elevated challenges. Thus, considerable attention should focus on the understanding and promoting strong quality of life for transition-age youth with autism. Young people with autism and their families need to be connected to the services and supports – both natural and formal – they need to experience a high quality of life.

Historical Background

During the 1970s, quality of life began to be widely studied across a number of diverse disciplines, and in the 1980s disability-related fields began to embrace the concept (Schalock 2000). However, during this early stage, researchers and service providers were embracing a concept that

was not well-understood or well-defined. Therefore, the later decades – throughout the 1990s, 2000s, and up until today – researchers have been attempting to address salient questions about the concept of quality of life for individuals with disabilities (Schalock 2000; Van Heijst and Geurts 2015). This includes research addressing the concept and quality of life specifically for different groups of individuals who share characteristics, such as transition-age youth with autism.

Current Knowledge

In the last decade, recent research has significantly contributed to understanding issues around the quality of life for individuals with disabilities. This section will summarize current knowledge specifically related to the quality of life of transition-age youth with autism in three areas: (a) measurement of the concept, (b) differences in quality of life between young people with and without autism, and (c) predictors of higher quality of life for this population.

First, the assessment of quality of life for young people with autism presents with a variety of challenges. The measures most frequently used in published papers to assess the quality of life of youth with autism include the PedsQL (Varni et al. 1999), Kidscreen (The KIDSCREEN Group Europe 2006), and Child Health Questionnaire (Landgraf et al. 1996). Each of these three measures uses Likert-type scales and has options for using self-report and proxy report. Although there are examples of the use of self-report to assess the subjective quality of life of youth with autism in the literature (e.g., Clark et al. 2015; Cottenceau et al. 2011; Kamp-Becker et al. 2010), these studies typically focus on high-functioning youth with average or above average measures of intelligence. There are additional challenges that arise when considering the use of self-report with young people with more complex support needs, including co-occurring intellectual disability and complex communication needs. Many have discussed how the difficulties with communication and cognition that can be associated with autism complicate being able to acquire reliable

self-report on subjective indicators of quality life (Biggs and Carter 2016; Clark et al. 2015). Thus, proxy-based responses are a popular alternative to self-report of quality of life, even though these reports have limitations. A majority of studies involving both self-report and proxy report for youth with autism suggest parents may rate quality of life lower than the youth themselves (Clark et al. 2015; Shipman et al. 2011; Van Heijst and Geurts 2015).

Second, findings from a number of studies indicate transition-age youth and young adults with autism have lower ratings of quality of life when compared with ratings of typically developing young people. In a meta-analysis of quality of life in individuals with autism across the life-span, van Heijst and Geurts (2015) found overall quality of life is lower for individuals with autism compared to individuals without autism. Furthermore, these differences were found consistently across the life-span. More specifically for transition-age youth, Kamp-Becker et al. (2010) found self-reported quality of life was lower for adolescents and young adults with high-functioning autism when compared with young people without a disability. Biggs and Carter (2016) found parent-proxy ratings of quality of life of their transition-age sons and daughters with autism (both with and without co-occurring intellectual disability) were significantly lower than normative ratings in the areas of social support, physical well-being, and psychological well-being. Collectively, these findings emphasize the importance of addressing aspects of quality of life as outcome measures for treatments and interventions for young people with autism. Moreover, across a number of studies focused on this population of young people, the greatest differences between ratings of quality of life when compared with typically developing peers are often found related to domains focused on social well-being and social support (e.g., Biggs and Carter 2016; Clark et al. 2015; Kamp-Becker et al. 2010). These findings further emphasize the importance social-related intervention and support strategies for this group of youth. Social-related intervention and support strategies for youth with autism can include communication interventions, social support and social skill

interventions, as well as high-quality inclusive learning opportunities (Biggs and Carter 2016).

Third, recent research has begun to understand the different factors that might predict or influence quality of life for transition-age youth with autism. Generally, however, what has dominated this area of research has been a focus on the contributions of demographic- and disability-related characteristics, such as age, gender, race/ethnicity, socioeconomic status, disability severity, adaptive behavior, and cognitive functioning (Schalock 2004). Each of these factors is related to fairly stable rather than malleable characteristics of youth, and the findings are mixed related to whether these different characteristics influence quality of life. For example, while some have found significant associations between quality of life and disability-related characteristics (e.g., support needs, functional abilities, or challenging behaviors), others have not (e.g., Biggs and Carter 2016; Kamp-Becker et al. 2010).

While there is limited and mixed knowledge about associations between these demographic- and disability-related characteristics with quality of life, even less is known about other, more malleable factors. Such factors that may be associated with quality of life – but also are more likely to be able to be positively influenced by intervention efforts – include young people's access to support-related resources (e.g., social resources and support, relationships, spiritual faith), their dispositions or personal characteristics (e.g., positive character strengths, self-determination), and their community involvement (e.g., participation in out-of-school activities). Research is only beginning to explore whether these types of factors might be associated with higher quality of life for young people with autism. For example, Biggs and Carter found greater involvement in out-of-school activities (e.g., athletics, volunteer experiences, community activities) and strength of religious faith were both associated with quality of life ratings within the domain related to social well-being. Furthermore, the character strengths of young people (e.g., courage, empathy, gratitude, humor, resilience) emerged as a strong predictor of higher quality

of life across all domains. Although other studies have linked factors like community involvement to various positive outcomes for young people with and without disabilities (e.g., Mahoney et al. 2006), few studies have directly explored whether these types of malleable factors have predictive relationships with quality of life.

Future Directions

A number of important areas related to quality of life for this population need further investigation, pointing the way for future research directions. First, a number of questions remain related to measurement of quality of life for transition-age youth with autism. Few efforts have focused on integrating subjective and objective indicators of quality of life into a single measurement tool, which may be well-suited to assessing the complex and multidimensional concept. The field also needs more information to better understand differences between using self-report and proxy report to assess subjective indicators of quality of life, and the influence of who does the reporting in proxy reports (e.g., mother versus father) has not yet been thoroughly investigated. Finally, additional research is needed to identify and develop ways to reliability and validly capture the views of youth with significant co-occurring cognitive and communication impairments through self-report on their own quality of life.

Second, current studies provide snapshots of quality of life of young people with autism at single points in time. While these cross-sectional investigations are important, future research is needed that also addresses longitudinally how quality of life for individuals with autism changes over time.

Third, more research is needed to further explore factors that may be associated with higher quality of life for young people with autism. Identifying the significant predictors of quality of life can be a critical step in developing effective interventions, supports, and services to help individuals with autism live a life of quality. This may be especially true if investigators are

successful in isolating the influences of more malleable factors in a young person's life, rather than focusing exclusively on rather fixed factors such as disability- and demographic-related characteristics. At the present time, few studies have explored these types of factors that may be targeted by intervention, such as community involvement, access to supportive relationships, involvement in faith communities, and positive characteristics such as humor, empathy, resilience, and self-determination.

Educators, therapists, and other service providers are charged with the task of providing services and supports that lead to quality outcomes for individuals with autism. Focusing on issues around quality of life can help these and other stakeholders support individuals with autism in living a life of quality throughout the life-span, including during this critical period of transition.

Definition

Quetiapine is a prescription drug in the group of atypical antipsychotics initially FDA-approved for medical use in the year 1997 whose active ingredient, quetiapine fumarate, has the chemical formula $C_{25}H_{31}N_3O_6S$. This drug, marketed by AstraZeneca, is FDA-approved for the treatment of global symptoms, positive symptoms, negative symptoms, cognition, and aggression in

schizophrenia, the treatment of bipolar disorder, and as an adjunctive treatment of major depressive disorder. Quetiapine has also been used in open-label trials in autism spectrum disorders (ASDs) targeting irritable behaviors marked by aggression, self-injury, and severe tantrums. Observed side effects include agitation, sedation, weight gain, aggression, and sialorrhea, and this drug has a low risk of anticholinergic effects, orthostasis, and increased liver enzyme levels and a very low risk of extrapyramidal symptoms, neuroleptic malignant syndrome, seizures, and hematologic effects.

RAADS-R

Ariella Riva Ritvo
Child Study Center, Yale School of
Medicine, Yale University, Los Angeles,
CA, USA

Synonyms

[Ritvo autism asperger diagnostic scale – revised](#)

Description

The RAADS-R is an 80-item scale specifically designed to assist clinicians diagnosing AD in adults 18 years and older. It contains a total of 80 questions. Sixty-four short questions identify symptomatic behaviors that are scored on a four-point Likert scale that takes into account developmental factors (true now and when I was young = 3, true only now = 2, true only when I was younger than 16 years old = 1, and never true = 0). It also contains 17 non-symptomatic questions that are scored in reverse order (true now and when I was young = 0, true only now = 1, true only when I was younger than 16 years old = 2, and never true = 3). These 16 questions are identified on the scale by an asterisk next to their question number.

Historical Background

The original version of the Ritvo Autism Asperger Diagnostic Scale (the RAADS) was developed to assist clinicians diagnosing autistic disorder in adults (18 years and older). It contained 78 items based on DSM-IV TR symptom criteria. After extensive field testing, the scale was modified by the elimination of three questions and the addition of five new questions. The revised 80-question scale is called the RAADS-R. A Swedish version of this scale has been published, and translations into other languages are being conducted Andersen et al. (2011).

Psychometric Data

The RAADS-R was validated in an international study conducted at nine medical centers on three continents (North America, Europe, and Australia). It involved 201 autistic disorder adults and 578 comparison cases (276 who never had a DSM-IV TR diagnosis and 302 who had a DSM-IV TR diagnosis other than autistic disorder). Results revealed the following: sensitivity = 97% (proportion of actual positives correctly identified), specificity = 100% (proportion of negatives correctly identified), concurrent validity = 96% when compared with other diagnostic instruments (ADOS Module 4, SRS), and test retest reliability $r = .987$.

Clinical Uses

To administer the RAADS-R, a diagnostician reads each question to the subject and marks the answer sheet. This insures that the questions are understood, the answers are properly coded, and the score can be quickly determined. Most importantly, however, it gives the diagnostician a chance to identify and discuss specific symptoms during administration. The average time to complete and score the RAADS-R is 30 min.

A total RAADS-R score of 64 or higher is consistent with the diagnosis of AD and supports the clinician's diagnosis. However, if there is difference between the clinician's diagnosis and the RAADS-R diagnostic assignment, the clinician's diagnosis should take precedence. This is because symptoms may be revealed only during an interview. Also, the RAADS-R standardization study reported that many AD subjects, particularly those in their late teens and early twenties, failed to acknowledge the presence of symptoms that their families said were present and which were readily observed by the diagnostician.

Rank, Beata

Fred R. Volkma
Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Names and Degrees

Beata Rank (Minzer): February 16, 1886–April 11, 1967

Major Appointments (Institution, Location, Dates)

- 1918–1926: Psychoanalytic training with Sigmund Freud in Vienna, Austria
- 1926–1936: College training in France
- 1936–1967: Child psychoanalyst in Boston Mass

Landmark Clinical, Scientific, and Professional Contributions

A child psychoanalyst who trained with Freud (among others), Beata Rank was an honorary Professor of Psychiatry at Boston University School of Medicine as well as a consultant/supervisor at the Judge Baker Guidance Center in Boston. Along with Marian C. Putnam, she both cofounded and codirected the James Jackson

Putnam Children's Center (1943). This Center was unusual in its emphasis on work with young (preschool) children and their parents. In the field of autism, her publication on unusual patterns of development (what she termed atypical development) was an early and highly original contribution prefiguring, in some ways, the notion of atypical PDD in DSM-III (1980).

Short Biography

A native of Poland, Beata Rank had an early interest in psychology and met her husband Otto, a psychoanalyst and student of Freud's, and wed him shortly before the conclusion of World War I. The couple moved to Vienna where they were very much part of the psychoanalytic circle centered around Sigmund Freud. She trained in psychoanalysis and worked on issues related to women's development and childhood. As her husband's relationship with Freud began to deteriorate, the couple moved to Paris for a time before Otto moved onto the USA. She continued her study of women's issue and eventually joined him in the USA. Within the Boston psychoanalytic community, she was accepted as a psychoanalyst and worked at Boston University as well as at the Judge Baker Child Guidance Center. At the Putnam Center, which she cofounded, she began a day treatment program for younger children and began to write about the emotional and cognitive problems of this age group. Her papers on atypical development (which prefigured, in some ways, the concept of PDD-NOS) were published during this time.

Rapid Motor Imitation Approach (RMIA)

Trina D. Spencer
 Rightpath Research and Innovation Center,
 University of South Florida, Tampa, FL, USA
 Institute for Human Development, Northern
 Arizona University, Flagstaff, AZ, USA

Definition

The rapid motor imitation approach (RMIA) involves the quick performance of a massed set of large and/or small motor imitative responses prior to vocal imitation opportunities. This procedure was designed to facilitate transfer of imitation from motor to vocal modes of responding. In research applications of RMIA, a sequence of low effort motor imitation trials have been used to prime imitation of vocal responses in children with autism or developmental disabilities with no vocal behavior. There have only been a few examples of this approach applied in research, and the phenomenon responsible for inducing imitation across response modes is unknown. Generalized imitation training, behavioral momentum, and teaching arrangements that increase the value of consequences for vocal imitation have been offered as possible explanations.

Rapid Prompting

James T. Todd

Psychology Department, College of Arts and Sciences, Eastern Michigan University, Ypsilanti, MI, USA

Definition

The Rapid Prompting method (aka RPM, Rapid Prompting, Soma[®] RPM, Informative Pointing, Spelling to Communicate, and S2C) is a teaching, therapeutic, and communication technique attributed to Soma Mukhopadhyay of the Halo-Soma Institute (Austin, TX) intended to establish independent, cognitively sophisticated pointing-,

typing-, or writing-based communication in people who are nonverbal due to autism (Friðriksson 2009; Iversen 2006, 2007; Mukhopadhyay 2008). Ostensibly based on Jean Piaget's developmental psychology (e.g., Piaget 1930) and A. Jean Ayres's theory of sensory integration (Ayres 1979), Rapid Prompting is similar to the discredited intervention Facilitated Communication (FC; Todd 2015; Tostanoski et al. 2014) in regarding autism as being substantially an expressive disorder (Crossley 1994), but superficially resembles in implementation the discrete trials methods of applied behavior analysis (ABA; Maurice et al. 1996). The subject, who is supposedly prevented by autism from displaying potentially considerable hidden literacy, selects a written response to a question or statement from a set of alternatives in a series of "teach-ask" trials that increase in complexity as the intervention proceeds. In the standard implementation, choosing a single item from a small set of choices expands to spelling out verbal responses by pointing to individual letters on a printed letter board. Thus, in practice, Rapid Prompting differs from FC in that the aide holds and moves the letter board in front of the subject rather than using physical and other prompts to guide the subject's pointing. However, as in FC, a verbally skilled individual physically or otherwise intervenes the production of the output attributed to the nonspeaking person – whether by moving the subject relative to the letters or the letters relative to the subject (see Todd 2015). Some reports suggest that the aide's assistance is not motivational as claimed by Rapid Prompting advocates; accurate responding may not occur unless the aide knows the answers (see Iversen 2006, pp. 242–248, 2007, p. 54). Also as in FC, the collection of ongoing performance data and the objective evaluation of authorship are very strongly discouraged (Halo-Soma n.d.; Iversen 2006, pp. 242–248; Mukhopadhyay 2008, pp. 16–17). To date, there are no published, methodologically sound studies of the effectiveness of Rapid Prompting for establishing reliable, independent communication in nonverbal people with autism (Lang et al. 2014; Schlosser et al. 2019).

Historical Background

Rapid Prompting was developed by Soma Mukhopadhyay, whose main professional training is in chemistry, from a collection of informal methods she claims to have used to teach her son Tito to communicate via handwriting and typing despite him having severe autism and little functional speech, (Iversen 2006; Mukhopadhyay 2008). Earning notice in India and the United Kingdom in the late 1990s, Mukhopadhyay and her son were profiled in the BBC documentary, “Tito’s Story,” in which her abilities as a teacher and his status as an avatar of hidden literacy were enthusiastically endorsed by autism professionals (see, e.g., Wing 2000/2003). In 2001, Mukhopadhyay was brought to the United States by Portia Iversen and Jon Shestack’s Cure Autism Now (CAN) Foundation. As chronicled in Iversen’s (2006) book, *Strange Son*, more endorsements followed, along with considerable mainstream media attention. Features by *60 Minutes II* (Kohn 2009), PBS (How does the autistic brain work? n.d.), *The New York Times* (Blakeslee 2002), *National Geographic* (Mind Tree Poems 2005), and *Scientific American* (Mukerjee 2004) represent just some of that early coverage. Supplementing the mainstream features were books of poetry, essays, and stories attributed to Tito Mukhopadhyay (2000, 2003), descriptions of Rapid Prompting in popular autism guidebooks (e.g., Sicile-Kira 2004), and a large number of items on the Internet.

Mukhopadhyay was based in California until 2004 when she moved her operation to what is now the Halo-Soma Institute in Austin, Texas. From Halo-Soma, Mukhopadhyay provides clinical services, presents internationally, and runs workshops. Halo-Soma does not conduct evaluation research, and Mukhopadhyay has published several works on Rapid Prompting including an instructional guide: *Understanding Autism Through Rapid Prompting Method* (Mukhopadhyay 2008), and a lesson supplement, *Curriculum Guide For Autism Using Rapid Prompting Method: With Lesson Plan Suggestions* (Mukhopadhyay 2011). An expansive website sponsored by Halo-Soma is its only other

comprehensive source on Rapid Prompting proper, featuring both free and subscription-restricted multimedia content (Halo-Soma n.d.). Iversen, who no longer collaborates with Mukhopadhyay, developed her own version of Rapid Prompting called “The Informative Pointing Method,” which she disseminates electronically from her “Strange Son” website (Iversen 2007). Another variant, “Alphabet Therapy” from Vanderbilt University, was said to combine ABA and Rapid Prompting procedures and is directed at people with Angelman Syndrome (Valle et al. 2008).

Attention to Rapid Prompting in the media, popular press, and on the Internet continues to expand. This includes not only more profiles of Mukhopadhyay and her son but a growing number of books and other accounts of individuals said to have achieved full literacy through the method (e.g., Bonker and Breen 2011; Burns and Wambua 2009; Sicile-Kira 2010). In 2009, both Soma Mukhopadhyay and Rapid Prompting were prominently featured in the Icelandic documentary “Sólskinsdrengrurinn” (Friðriksson 2009; literally, “The Sunshine Boy”; retitled “A Mother’s Courage: Talking Back to Autism” for distribution in English by Home Box Office). “Sólskinsdrengrurinn”/“A Mother’s Courage” followed Margrét Dagmar Ericsdóttir as she traveled to England and then the United States in search of help for her son’s condition, with approximately the final third of the movie devoted to the supposedly successful implementation of Rapid Prompting. FC advocates, who share Mukhopadhyay’s assumption of hidden intelligence in people with autism, increasingly reference Tito Mukhopadhyay as an example of someone whose hidden intelligence was allegedly revealed by alternative treatment methods – while generally not saying much about the Rapid Prompting technique itself (see, e.g., Biklen 2005).

Rationale or Underlying Theory

Rapid Prompting procedures were developed through trial and error, and acquired a theoretical rationale later. According to Mukhopadhyay (2008,

pp. 33–53), autism is the result of the child’s potentially more advanced cognitive abilities being undermined by altered versions of the early Piagetian stages. The cognitive difficulties are further exacerbated by poor integration of multiple sensory inputs, as suggested by Ayres (1979). However, Rapid Prompting is said not to be primarily based on psychology, but “upon how the brain works” (Halo-Soma n.d.; Mukhopadhyay, personal communication, May 6, 2009). Thus, references to neuroanatomy and physiology appear throughout Mukhopadhyay’s 2008 book, the Halo-Soma website, and workshop presentations. Over- and under-activity of the mirror neurons lead to echolalia and withdrawal, respectively (pp. 42–44). “Underconnectivity” creates poor “central coherence” (p. 26). A functional laterality assumption suggests teaching from the subject’s right side to “activate the student’s left-brain for reasoning” (p. 185). Troublesome behaviors such as hair pulling and perseverations are said to be “instinctive” and arise in the caudate nucleus (pp. 211–215). Voluntary or “deliberate” actions arise in the putamen and ultimately work their way to the motor cortex (pp. 215–220). Obsessive behaviors are said to be associated with “extreme emotions” and potentially lead to aggression because “the caudate nucleus is very close to the amygdala” (p. 216). The general solution to the communication and behavior problems associated with autism is to “activate the reasoning part of the brain so that the student becomes distracted by and engaged in learning” (Halo-Soma n.d.). This is done by providing a series of cognitive challenges of graduated difficulty through the “dominant sensory channel” to repair the defective sensorimotor and preoperational cognitive structures and then continue to provide input that will force the advancement into the concrete and formal operational stages.

At a pragmatic level, Rapid Prompting shares with FC the “presumption of competence”: the assumption that nonverbal people with autism are likely to possess considerable hidden knowledge that they cannot express due to hypothesized motor planning impediments (Biklen 2005; Iversen 2006; Mukhopadhyay 2008). In other words – and in apparent contradiction to other

elements of Rapid Prompting theory – autism is a disorder that interferes with expression and cognitive integration, not necessarily the ability to absorb and process knowledge itself (Mukhopadhyay 2008, p. 132). The assumption of hidden literacy proscribes that Rapid Prompting training should begin with age-typical materials and concepts, such as multiplication and division for a 12-year-old, and abstract ideas rather than foundational ones, such as color and number. As in FC, the hidden literacy assumption also seems to explain the sudden appearance of linguistically sophisticated responding in otherwise nonverbal, profoundly affected subjects who have never participated in formal classroom instruction, sometimes the first time Rapid Prompting is used, sometimes at a much higher level than predicted by the subject’s age, and sometimes in a language other than the one the subject has been primarily exposed to (see, e.g., Bonker and Breen 2011; Burns and Wambua 2009; Friðriksson 2009; Kohn 2009). Skeptics attribute such performances to the teachers rather than the students (Spitz 1997).

Aside from seating position implications of laterality and the link between the hidden literacy assumption and teaching level, there is little clear relationship between Mukhopadhyay’s neurological conceptualizations and the elements of the Rapid Prompting training protocol. For instance, the solution to the problem of “instinctive actions” such as hair pulling does not seem particularly specific to the caudate nucleus. It is to simply ask the student whether the cause of the problem is being “tired” or “mad,” writing those words on separate pieces of paper, and finally telling a social story related to the word pointed to (Mukhopadhyay 2008, p. 185). This disconnect between the methods employed and their putative or actual empirical basis is particularly true of Rapid Prompting’s use of learning-based techniques of stimulus fading across match-to-sample trials of increasing complexity – a kind of errorless stimulus control procedure. Neither Mukhopadhyay’s multivolume book series (e.g., *Understanding Autism Through Rapid Prompting Method*) nor the Halo-Soma website references any relevant, modern procedural, empirical, or

theoretical work in learning theory, particularly on the subject of stimulus control and stimulus transfer (see, e.g., Wolery and Gast 1984).

Goals and Objectives

The goal of Rapid Prompting and its variants is to establish functional independent pointing-based communication in people who are otherwise non-verbal due to severe autism or other developmental disabilities: “RPM aims to develop the skill of pointing to spell and/or write” (Mukhopadhyay 2008, p. 209). In contrast to the comprehensive educational, social, and functional scope of applied behavior analysis and some other interventions, Rapid Prompting is not intended to directly remediate the behavior problems associated with autism, teach activities of daily living, or prepare the subject for independence (Mukhopadhyay 2008, pp. 206–209). However, proponents assert that Rapid Prompting establishes functional communication, which is expected to reduce some of the problems associated with autism because with it the subject can express needs and ideas. To the extent, the subject cannot control overt problem behaviors or is unable to exhibit normal reactions to social situations, he or she is expected to be able to communicate accurately about the expected reactions (p. 208).

Treatment Participants

Rapid Prompting is directed primarily at people with autism who have little or no effective verbal communication ability, who can select items by pointing. Although difficult-to-manage behaviors such as tantrums, self-injury, or aggression might practically preclude a person’s participation in Rapid Prompting, there are no specific contraindications based on age, gender, or other aspects of behavioral profile (Mukhopadhyay 2008, pp. 86–89). A willing and able teacher with good verbal and organizational skills – typically a parent – is needed to provide the training and ongoing communication support. Alphabet Therapy, while

directed at people with Angelman syndrome, did not seem to have any features that would limit its use to that condition.

Treatment Procedures

Rapid Prompting training consists of a series of “teach-ask” multiple-choice or written-response trials that increase in difficulty as treatment progresses. The style of teaching is supposed to be dictated by the “open sensory channel” as indicated by behaviors such as self-stimulation (cf. Pashler et al. 2009). But the basic features of the training appear to be the same regardless of which sensory channel is presumed to be dominant. In a typical early training trial, the subject is given an item of information, then immediately queried about it. The subject might be told, “A triangle has three sides.” Then, as the teacher provides a set of response alternatives including the correct answer, asked “How many sides does a triangle have?” Early in the training, the response required could include selecting a single object, picture, letter, digit, or written word from two or more alternatives placed in front of the child. Later, it would include composing verbal statements by sequentially choosing letters from a letter board held by the teacher. Responding is prompted by specific actions of the teacher, such as putting a pencil (used as a pointer) in the subject’s hand after the question is asked. The pencil is removed from the subject’s hand to signal the end of each trial (see Mukhopadhyay 2008, pp. 127–178). In some implementations, the pencil is pushed through the holes associated with letters and numbers in plastic alphanumeric stencils – the holes said to make selecting easier. The stencils may also be used to guide letter formation if printing is to be taught. However, the stencils are usually replaced by a laminated letter board that the subject points to either with the pencil or sometimes with just the finger (see, e.g., Nonverbalautismmom 2010).

Mukhopadhyay encourages teachers to use words rather than pictures or objects and to write each of the response options by hand on pieces of paper torn from larger sheets during the trials.

(The use of torn paper is so fundamental to Rapid Prompting that it is depicted on the cover of Mukhopadhyay's 2008 and 2011 books.) Thus, in a typical teaching trial the teacher would:

1. Make a statement.
2. Ask a question related to the statement.
3. Tear the needed number of sheets of paper from a larger piece of paper.
4. Quickly write the choices on paper pieces; one correct, the others distractors.
5. Place the choices in front of the subject.
6. Hand the subject a pencil for pointing, prompting to initiate as necessary.
7. Take the pencil from the student following the selection.
8. Collect all the paper, taping the torn pieces to a larger piece.

The sound of the paper tearing is said to focus the subject on the task and prompt immediate responding. The pieces may be slapped down loudly to add to the prompting effect (see Kohn 2009). Two to three trials per minute might be achieved if the subject responds immediately, and the answers do not take a long time to write. Explicit verbal directives to pay attention and respond quickly are also common. It is not unusual to see a teacher speak continuously and gesture frequently (i.e., give "air prompts") during the trials. The constant talking is said to help the subjects learn to attend to speech, particularly aiding those who "are more comfortable listening to environmental sounds than spoken language" (Halo-Soma n.d.). Hand-over-hand guidance of responding is not normally used except when it is needed to initially establish pointing or writing (Mukhopadhyay 2008, p. 129).

Escape or other disruptive behavior is dealt with physically. Subjects are kept in place by positioning them between the table and walls such that the teacher can block the subject's only escape route and is able to move away if the subject's behavior becomes unmanageable (see p. 185). Errors are corrected by verbal reprimands, trial termination, physical redirection using the stencil or letter board to push the subject's hands away. This can include slapping or shaking the

letter board against the subject's face or chest (see Friðriksson 2009; Iversen 2007, p. 25). Explicit reinforcement of correct responses is not considered necessary, although incidental verbal praise embedded in feedback about accuracy is common (Ochs et al. 2005). Collecting ongoing performance data is strongly discouraged (Mukhopadhyay 2008), although video recordings are sometimes made (see Ochs and Solomon 2010), and stimulus materials from sessions may be retained (Mukhopadhyay 2008). According to Mukhopadhyay (2008, pp. 16–17), data collection is unnecessary and stigmatizing. The Halo-Soma website reports: "Soma does not use data sheets. She feels taking down hash marks interrupts the flow of instruction and inhibits the student's performance and success."

Despite its very heavy dependence on multiple forms of prompting, Rapid Prompting includes no procedures to either prevent the development of or test for "prompt dependency" – responding by the subject influenced by conscious or unconscious cues from teacher such as looking at the answer or frequently placing the correct choice in the same relative position. Such protections are more than justified by the use of prompt-fading procedures. But they are essential because: (1) facilitator influence is strongly suggested by reports of astonishing literacy suddenly appearing in people who were previously entirely nonverbal and showed no previous signs of such talents (Bonker and Breen 2011; Burns and Wambua 2009; Friðriksson 2009; Iversen 2006; Kohn 2009; Mukhopadhyay 2008); (2) there are several reported instances in which correct answers were not given unless the teacher was aware of the needed information – including a message-passing test in which Mukhopadhyay and her son were unable to correctly answer a single question about a story Mukhopadhyay had not heard (Iversen 2006; see especially pp. 242–248; 2007, p. 54); (3) video recordings of Rapid Prompting with letter boards seem to show the person holding the board subtly moving each letter toward the subject's finger, with the subject responding by moving his or her finger toward the letter (e.g., Friðriksson 2009; Nonverbalautismmom 2010); (4) research on facilitator influence in FC clearly

demonstrates that teachers can be unaware of authoring responses even when they are physically holding the subjects' hands (Shane 1994); (5) over a century of research on communication, particularly studies on the phenomenon of automatic writing, has revealed how the unconscious composition of complex verbal output can be engendered and maintained by Rapid Prompting-like situations (Spitz 1996); and (6) the procedures used in Rapid Prompting – fading verbal and gestural prompts for selecting among a small number of discrete items and then expanding the number of choices – very closely replicate the Pinchbeck Technique, a method conjurers have used for centuries to create the illusion of letter-by-letter communication (Pinchbeck 1805). Pinchbeck himself warned of the development of unconscious cueing of letter selections by the conjurer (Pinchbeck 1805, p. 26).

Efficacy Information

Mukhopadhyay claims to have treated hundreds of individuals, presumably successfully (Mukhopadhyay 2008, p. 2). Over 300 clients, mostly children, were pictured and partially identified on the Halo-Soma website. Other Rapid Prompting providers make similar claims. Yet, there are no published, methodologically sound, peer-viewed experimental studies examining the overall effectiveness of Rapid Prompting or its variants, nor are there any published objective evaluations of the validity of communications attributed to individual subjects (Lang et al. 2014; Schlosser et al. 2019). Indeed, the principal advocates of Rapid Prompting range from being dismissive of to expressly hostile to ongoing data collection and scientific tests of authorship (Iversen 2006, pp. 242–248; Mukhopadhyay 2008, pp. 16–17). Iversen, for instance, described the objective evaluation of authorship as a “crime” (Iversen 2006, pp. 242–248). Two published studies are said to demonstrate hidden cognitive competence based on Rapid Prompting (Chen et al. 2012; Jaswal et al. 2020). Those claims remain unfounded primarily due to the failure to the procedures used to clearly establish

that the subjects (rather than the aides) authored the output (Tostanoski 2014; Vyse 2020). Nevertheless, the efficacy of the method is all but assured by advocates. University of California San Francisco Emeritus neurologist Michael Merzenich, for instance, stated on the television program *60 Minutes II*, “I think it’s almost certain that this method can be used on many autistic children. In fact, the initial indication from these studies is that it might apply to the substantial majority of these children” (in Kohn 2009). Head of the Autism Research Institute and advocate of the DAN! biomedical protocol, Barry Edelson (Halo-Soma n.d.), has stated, “If my child had a limited verbal skills, I would look into the Rapid Prompting Method.” No objective evidence was provided to support these claims and recommendations, nor have the “studies” referred to by Merzenich appeared in the scientific literature (see Iversen 2006). According to Mukhopadhyay, the appropriate measures of the efficacy of Rapid Prompting are standard educational assessments – although doing such assessments with Rapid Prompting would necessarily raise the same questions of independence and authorship as would be raised by the use of FC.

Due to the lack of empirical support for Rapid Prompting, and its many procedural and conceptual similarities to Facilitated Communication, the American Speech Language and Hearing Association (ASHA) has issued a statement against its use (ASHA 2018). The statement begins:

It is the position of the American Speech-Language-Hearing Association (ASHA) that use of the Rapid Prompting Method (RPM) is not recommended because of prompt dependency and the lack of scientific validity. Furthermore, information obtained through the use of RPM should not be assumed to be the communication of the person with a disability.

Outcome Measurement

The validity of Rapid Prompting output could be assessed by effectively blinding the aide to the information asked of the subject. No such assessments have been published. There are no other standardized evaluations of Rapid Prompting.

Essentially, Rapid Prompting is presented as an augmentative or alternative communication (ACC) method, the use of which will make it possible to administer other kinds of standardized evaluations. Mukhopadhyay's first book (2008) contains a full chapter on administering tests using Rapid Prompting. However, those are not guidelines for formal evaluations, but rather advice on generating multiple-choice questions. There are no established standardized tests or assessments that have been normed for use with Rapid Prompting. The responsible and ethical administration of standardized tests would preclude use of scientifically discredited and unestablished communication interventions such as Facilitated Communication, Rapid Prompting, and their many variants. The direct physical intervention of the aide in producing test responses would call the validity of the test results into question.

Qualifications of Treatment Providers

There are no publicly recognized standards, regulations, or laws for registering, licensing, or certifying Rapid Prompting treatment providers. There are no listed university degree or certificate programs on Rapid Prompting as a clinical profession. The Halo-Soma Institute itself sponsors no recognized credentialing and seems to have published no professional or ethical standards of its own—although it appears to bestow a variety of titles suggesting formal certification (Halo-Soma n.d.). Thus, status of Rapid Prompting providers as professional therapists, psychologists, teachers, or aides is, at best, uncertain. The Halo-Soma organization has offered extended training workshops for selected application. However, most RPM training is appears to be provided directly to employees and clients through centers and in training workshops.

Rapiflux

► Fluoxetine

Rapun, Isabelle

Deborah Fein
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Name and Degrees

Isabelle Rapin, MD, University of Lausanne Medical School.

Major Appointments (Institution, Location, Dates)

1953–1954: intern in Pediatrics, Bellevue Hospital/New York University Medical School
1954–1958: resident in Neurology, Fellow in Child Neurology, Neurological Institute of NY – Columbia Presbyterian Hospital, Columbia University College of Physicians and Surgeons
1957–1958: Columbia University College of Physicians & Surgeons, Assistant in Neurology
1958–2012: Faculty, Albert Einstein College of Medicine. (1972–2012: Professor Saul R. Korey Department of Neurology, Department of Pediatrics, [Neurology])

2012–2017: Professor Emerita of Neurology and Pediatrics (Neurology), Albert Einstein College of Medicine, Bronx, NY

Major Honors and Awards

Dr. Rapin has been recognized as an early leader in child neurology by most major professional societies. She served as an officer of the Child Neurology Society, the International Child Neurology Association, the American Academy of Neurology, the American Neurological Association, and the International Neuropsychological Society. Her work was supported by research grants from the National Institutes of Health, the March of Dimes, and autism foundations. She has received multiple honors and awards from US and international organizations for her work on genetic diseases of children; childhood deafness; and causes of intellectual disability, autism, and childhood epilepsy. She has received lifetime awards for her teaching of medical students, residents, and fellows; in 2008 she received the Lifetime Achievement Award from the International Society for Autism Research and in 2010 the President's Award from the American Academy of Neurology. She served on the editorial board of multiple major journals in neurology and neuropsychology.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Rapin authored one book and coedited 10 books on child neurology, including two volumes on Child Neuropsychology for the Handbook of Neuropsychology. She published about 100 chapters and 183 articles in scientific journals (including *Science*). These have ranged from identification of progressive genetic and other diseases of the brain in her patients to methods of testing neurological function, to elucidations of the functioning of the auditory, visual, and motor systems, to issues of classification in developmental and psychiatric illnesses, to normal and abnormal development of higher cortical functions in children. One unique contribution is her important

theoretical and empirical papers about the relationship between sensory stimulation and development of higher cortical functions, including those affecting autism (see References).

Dr. Rapin has been a strong advocate for families with affected children and has won the devotion of these families with her reputation for direct and clear communication about all aspects of their child's condition. Dr. Rapin thinks broadly and deeply across disciplinary lines, promotes the careers of colleagues in her own and related disciplines, allowing her to formally and informally train many US and international colleagues in neurology, pediatrics, neuropsychology, language and communication disorders, and the nosology of disease.

Short Biography

Dr. Rapin was born in Lausanne, Switzerland, the eldest of three children, to a Swiss father and an American mother. Her mother, who belonged to a close-knit Connecticut family, met a young professor of French when she spent a summer in Lausanne as a Vassar student. They were engaged during the winter she spent at the Sorbonne in Paris after graduation. Thus, Dr. Rapin grew up in a bilingual Swiss home lined with books, where reading aloud in French or English, listening to music, and talking to interesting guests from many countries invited to tea or dinner were commonplace. Dr. Rapin remembers the war years in Switzerland as hated freezing winters with a sad mother completely cut off from her American family. Dr. Rapin decided to become a doctor when she was 10 years old, her interest having been piqued by the differences between active and passive immunity; despite literary parents, her sister became a research biologist and her brother a professor of computer science. She started at the Lausanne medical school after the war and graduated as a physician in 1952. Fascinated by neurology from the start, she discovered child neurology during a 1951 rotation in Paris; however, training was nonexistent in Switzerland or in fact anywhere. After completing the archival

work for a clinical neuropathology doctoral thesis, she moved to NY, where she became a Diplomate (Neurology), of the American Board of Psychiatry and Neurology in 1960, with Special Competence in Child Neurology in 1968. She served on the faculty of Columbia College of Physicians and Surgeons and Albert Einstein School of Medicine until her retirement from active practice in 2012, having trained many generations of child neurologists and evaluated and treated several thousand children. She lives in upstate New York and continues her scholarly work in writing and reviewing as Professor Emerita in Neurology and Pediatrics (Neurology). She is married to Harold Oaklander, Ph.D., and has four children and four grandchildren.

After this biosketch of Dr. Rapin was written, she passed away after a short illness, on May 24, 2017. She is deeply mourned by her family, colleagues, trainees, and patients.

Definition

The Research Domain Criteria (RDoC) project was initiated by the National Institute of Mental Health in 2009 to develop a novel classification of psychopathology. It represents a framework that explicates genes, brain, and behavior dimensions across heterogeneous categories of mental disorders (Insel and Wang 2010). As opposed to the symptom-based, categorical approach used to diagnose mental health conditions, the RDoC framework considers psychopathology based on disorders of brain circuits using genetics and neuroscience research tools to discover the biosignatures that can inform diagnoses and treatment of mental illness. The RDoC constructs are organized in a matrix containing five primary domains: negative valence, positive valence, cognitive systems, social processes, and arousal/regulatory systems. Each domain includes constituent constructs and seven units of analysis (e.g., genes, circuits, behavior).

The RDoC framework offers a new way of characterizing features of autism spectrum disorder (ASD) given the phenotypic heterogeneity in ASD (e.g., verbal abilities, cognitive functioning, social interests) representing continua that extend into normative ranges. For example, the social processes domain includes constructs that bridge social behavior with circuits of attachment, social dominance, and perception/understanding of self and others. The neural underpinnings of social behaviors, such as eye gaze and emotion recognition, have been studied with various neuroimaging and electrophysiological methods in order to establish biomarkers of ASD. In addition, the RDoC framework may be valuable in understanding the underlying mechanisms of co-occurring conditions in ASD. For example, anxiety is prevalent in individuals with ASD. However, using the current categorical approach, it is challenging to discern whether anxiety represents a true comorbidity or is unique to autism and underpinned by a distinct pathophysiological mechanism.

Current research using the RDoC framework in ASD has suggested conceptualizing ASD symptoms along positive, negative, and

cognitive dimensions, similar to a dimensional approach traditionally used for schizophrenia. Positive features could include behaviors infrequent in typically developing (TD) individuals (e.g., repetitive behaviors, echolalia, and circumscribed interests); negative features could reflect the absence of behaviors expected in TD individuals (e.g., eye contact or reciprocal social interactions); and cognitive features could include patterns of thinking and behavior common in ASD (e.g., rigidity of thinking, impaired attention).

The use of dimensional measures to capture variation in traits across individuals may leverage the discovery of neural correlates of ASD symptom-dimensions or brain-behavior associations in ASD. Thus, findings from functional MRI studies suggest that anxiety in ASD could be associated with aberrant activity of the amygdala, implicated in emotion processing, under the negative valence domain (i.e., acute threat or fear) (Herrington et al. 2017) as well as with aberrant activity of the nucleus accumbens, implicated in reward processing, under the positive valence domain (i.e., reward learning) (Richey et al. 2014). Within the social processes domain, the perception of self and others construct has been used to examine brain regions involved in social cognition in individuals with ASD and with schizophrenia using tasks of social-cognitive processing such as perspective taking (Eack et al. 2017).

Another overarching goal of the RDoC approach is to accelerate research supporting precision medicine that produces treatments tailored to the individual patient's pathophysiology of the disorder and predictors of response to a given intervention. For example, an investigation of neural-systems-level targets of behavioral therapy for associated symptoms in ASD, such as irritability and aggression under the frustrative nonreward construct, can shed light on neural markers and predictors of treatment response (Sukhodolsky et al. 2016). Further, integration of information from neuroimaging and genetics could be helpful in determining a dimensional, biologically driven classification of mental illness. Next steps for the RDoC project include

the need to develop new constructs and domains. For example, emotion regulation is currently considered an implicit component in many RDoC constructs (e.g., control of fear or impulsive behaviors), while there is emerging evidence that emotion regulation may be transdiagnostic and require an explicit role in the RDoC matrix (Aldao et al. 2016).

[Attachment disorder](#); [Disordered attachment](#)

Short Description or Definition

Children with reactive attachment disorder (RAD) or disinhibited social engagement disorder (DSED) exhibit abnormal social and attachment-related behaviors before the age of 5 years. According to the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5)*, and the *International Classification of Diseases, 10th revision (ICD-10)*, these are stress-related disorders, and the symptoms occur in consequence, i.e., following, or in reaction to, pathogenic caretaking of the child in the early years of life.

In the DSM-IV, the RAD diagnosis included two subtypes, characterized by different behavioral patterns. In the inhibited or withdrawn type, children avoid comfort, seem afraid to seek it, do not respond to it, and even resent comfort offered to them by caregivers. Failure to develop attachments to any caregivers is the essence of this disorder. In the disinhibited or indiscriminate type, children are unselectively attached to familiar as well as unfamiliar figures. This disinhibited subtype is now considered in the DSM-5 as a separate diagnosis, the disinhibited social engagement disorder (DSED). Socially disinhibited behavior with strangers is the core feature of these disorders. Both disorders are caused by

social neglect in childhood, presenting with distinct behavioral manifestations, prognosis, and vulnerability factors, and were therefore redefined as distinct disorders.

Some children who are diagnosed with autism spectrum disorders (ASD) may present behavioral symptoms that resemble the clinical picture of RAD or DSED. However, it is well established that autism does not result from, nor is a reaction to, inadequate caretaking. Therefore, these diagnoses are exclusive, and children diagnosed with an ASD cannot receive an additional diagnosis of RAD or DSED, even if they manifest resembling symptoms. Moreover, RAD and DSED can be diagnosed only if symptoms do not meet criteria for ASD and if symptoms cannot be accounted for solely by developmental delay.

Categorization

RAD first appeared in the third version of the DSM in 1980. In this early version of the disorder, growth failure, lack of social responsivity, and evidence of physical and emotional neglect were the central features, with onset by the age of 8 months. The DSM-III definition did not include the need to evaluate children for ASD or developmental delay. In the DSM-III-R, the link to growth failure was excluded, and the age of onset was changed to the first 5 years of life. In 2003, a task force of the American Academy of Child and Adolescent Psychiatry (AACAP) proposed a set of empirically based diagnostic criteria for RAD. These modified criteria include the requirement for pathogenic caregiving, as stipulated in the *DSM-IV* (e.g., persistent disregard of the child's basic physical or emotional needs or repeated changes of primary caregiver). The two behavioral subtypes were first introduced in this version and persisted in the DSM-IV and DSM-IV-TR. The new behavioral criteria for the two RAD types focused more on specific attachment behaviors. The DSM-5 and the ICD-10 now include RAD and DSED as separate disorders (Zeanah et al. 2016).

The diagnostic criteria for RAD and DSED usually refer to toddlers and young children, and

the majority of research conducted on RAD and DSED has been conducted on young children. Moreover, the attachment behaviors that are used for RAD and DSED diagnoses are not developmentally adapted for older children or adults. Therefore, diagnosing RAD or DSED in older children is more complicated, and less is known about the manifestation of these disorders in older children and adolescents. Additionally, inasmuch as the *DSM* requires that the symptoms are present before the age of 5, a reliable history is necessary but in many cases of older children is unavailable (Boris and Zeanah 2005).

Epidemiology

It is rather difficult to estimate the true prevalence of RAD and DSED because there is paucity of systemic data derived from the general population. Moreover, clinically validated data are not always available on neglected, abused, or institutionalized children. The prevalence of RAD has been estimated at 1% of all children under the age of 5 (Richters and Volkmar 1994). Obviously, the prevalence of RAD and DSED is elevated among high-risk populations, and several researchers reported that 30–40% of children, who entered foster care or were institutionalized at a young age, manifest significant symptoms pertaining to RAD or DSED (Rutter et al. 2004; Smyke et al. 2002; Zeanah et al. 2002, 2004, 2016).

Natural History, Prognostic Factors, and Outcomes

Children who are abused or neglected early in life are at risk for RAD and DSED. These risk groups may include children whose parents are alcohol or substance abusers or mentally ill because these parents are most likely not able to respond to the child's physical or emotional needs in a reliable and sensitive way. Those young children who are most severely neglected, physically or sexually abused, or abandoned are usually placed in foster care. These children are

at an even greater risk for the development of RAD or DSED. Earlier timing, increased severity, and prolonged duration of the period of maltreatment or institutionalization (specifically beyond the age of 6 months) all increase the risk for RAD or DSED. Yet, not necessarily all children who are neglected or abused will present this disorder.

Not much literature is available on the course of symptoms in older children and adolescents or on the outcomes and natural course over time. The only systematic data source is from the Bucharest Early Intervention Project. In this clinical trial, children in institutions were randomly selected to be placed in foster care and followed throughout childhood. The data from this study suggests that the recovery paths for the two disorders appear to differ. Institutionalized children who were later placed into more normative settings (adoption or foster care) frequently exhibit difficulties in attachments with the new caregivers, but they almost never meet the criteria for RAD. Nevertheless, indiscriminate social behaviors associated with DSED tend to persist over the years, even after significant improvement in the caregiving environment, the establishment of preferred and even secured attachment with new caretakers, and adequate functioning levels in everyday life (O'Connor and Rutter 2000; Rutter et al. 2007a; Zeanah 2000; Zeanah and Smyke 2008).

It might be the case that pathogenic caregiving that occurs at a critical time point leads to the development of DSED, and once it has developed, it becomes inherent in the child, even if later on, secure attachment is formed with specific caregivers who are now available to the child. Rutter et al. (2004) suggested that a form of biological programming, altering brain structure and functioning as an adaptive reaction to the environmental circumstances, occurs in children who experienced severe deprivation at a sensitive period of development (before the age of 6 months). The strong persistence of these unique behavioral patterns into middle childhood/early adolescence, as well as the effect of the timing and duration of deprivation, supports this assumption.

Clinical Expression and Pathophysiology

RAD and Attachment Classifications

As opposed to RAD or DSED, attachment classifications (secure vs. insecure) within the attachment literature (Ainsworth et al. 1978; Bowlby 1988) are not considered clinical entities or psychopathologies but rather developmental risk or protective factors. Attachment classifications for young infants and children are available in the context of a relationship with a primary caregiver. In contrast, RAD and DSED are clinical entities describing children's personality traits, uncoupled from a relationship with the primary caregiver (Zeanah and Smyke 2008).

RAD and DSED are the only diagnostic entities in the *DSM-5* that specifically relate to attachment. However, limiting possible disordered attachment patterns to the rather specific diagnostic criteria of a disorder may underestimate the clinical conditions related to attachment disturbances in general. There are diverse behavioral manifestations and diagnoses in addition to RAD or DSED that may be associated with, and at times attributed to, attachment disturbances (e.g., conduct disorder, anxiety disorders) and can be effectively treated with attachment-based therapeutic approaches. The current focus on rather narrow diagnostic criteria, which does not include conceptualization of attachment-related issues, leads to treatments that may address, and temporarily reduce, symptoms rather than provide treatment for the underlying pathology and deficits associated also with the underlying attachment history (Hardy 2007).

Evaluation and Differential Diagnosis

A childhood history of severe adversity is associated with elevated risk for psychopathology and developmental delays; therefore the comorbidity of RAD/DSED with other disorders is highly likely to occur. However, some conditions are exclusive and should be distinguished from RAD/DSED.

Developmental delays and language disorders that are also associated with early environmental

deprivation may be experienced by children diagnosed with RAD/DSED. Similar to RAD, some of these delays are treatable, and after improvement in the environment, some of the gaps are bridged (Boris and Zeanah 2005). Developmental or language delay and RAD/DSED are not exclusive diagnoses, but RAD/DSED diagnosis should not be assigned if the clinical picture can be alternatively explained by developmental or language delays. An important distinction is that children with delays do not usually present with difficulties in emotion regulation and social relatedness.

RAD and DSED may co-occur with medical conditions that are associated with neglect and maltreatment such as failure to thrive, growth disturbances, and other undiagnosed medical conditions that require treatment.

The possible association between institutionalization and autism was introduced by the Romanian adoption studies. Rutter and his team reported on an autistic behavioral pattern found in more than 10% of the children adopted out of Romanian institutions (Rutter et al. 1999, 2007b). This behavioral pattern resembled the behavioral characteristics of autism: social and communicational difficulties or abnormalities and stereotyped behaviors. However, the behavioral characteristics in this group of children changed and sometimes diminished over time and therefore were defined as "quasi-autism." These children were also reported to present disinhibited attachment behaviors, emotional problems, peer problems, inattention/overactivity, and cognitive impairment. Rutter et al. reported that as the children who were diagnosed with quasi-autism grew older, some of their difficulties seemed to have more in common with DSED than with autism. However, although there was a substantial association between quasi-autism and DSED, and for some children the latter dominated at age 11, the autistic features still persisted to some degree. Rutter et al. suggested that the early deprivation might cause alterations and deficits in social cognition, manifesting in disinhibited social behavior and in "quasi-autism," and emphasize the potential benefit of interventions aimed to improve social skills and develop healthy, close relationships

for post-institutionalized children in general (Rutter et al. 2007a, 2010). RAD, DSED, and ASD are exclusive diagnoses. ASD usually occurs in adequate caregiving environments and is not a result of pathogenic care, whereas RAD and DSED do not typically occur in adequate caregiving environments. Symptoms of RAD tend to dramatically improve after improving the environment, whereas ASD symptoms are more resistant. Additionally, the deficits in imaginative play, deviant language development (e.g., echolalia), deficient initiation, or response to joint attention do not typically appear in RAD/DSED but are rather common in ASD (Boris and Zeanah 2005).

DSED, characterized by deficits as social inhibitory control, is associated with attention deficit and hyperactivity disorder (ADHD) symptoms and deficits in cognitive inhibitory control, but these disorders usually occur independently of each other with different underlying deficits (Gleason et al. 2011). In ADHD, the impulsivity is usually behavioral and/or cognitive, but not always social, whereas in DSED it is always social.

Posttraumatic stress disorder (PTSD) has also been documented in maltreated and institutionalized children. However, the association between PTSD and RAD has not been officially documented. It has been suggested that RAD overlaps with and perhaps might be better conceptualized as PTSD or acute stress disorder (Boris and Zeanah 2005).

Assessment Methods

The AACAP published a practice parameter with guidelines for the diagnosis and treatment of RAD (Boris and Zeanah 2005). This parameter was updated in 2016 and includes guidelines for assessment of children with suspected RAD/DSED (Zeanah et al. 2016). First, screening for RAD and DSED in children with a history of extreme neglect or foster care is recommended. There is no valid screening measure, and the guideline for assessing risk is to inquire about the child's attachment behaviors with familiar and non-familiar adults and about the child's history.

An evaluation for RAD or DSED must include structured observations of the child interacting with primary caregivers, as well as with strangers. The detailed history of the child's early attachment behavior and caregiving environment, obtained from several resources, is necessary as well. It is also important to gain information about the child's behavior in different settings (i.e., home, school/early learning setting). An interaction with a stranger is necessary for assessing DSED. If any suspicion regarding current or previous maltreatment arises, it should be reported to the responsible authorities. Additionally, children with RAD or DSED need further evaluation for developmental delays and language disorders as well as a pediatric examination for medical conditions that might be undiagnosed and untreated. A psychiatric evaluation is necessary in order to assess comorbid conditions.

Marvin and Whelan (2003) suggest a complementary approach for an assessment protocol of RAD. In their work, they combine terminology of the four attachment patterns with the *DSM* criteria and *ICD-10* coding. This protocol includes standardized assessment tools, clinical open-ended interviews with the parents and child, and clinical observation of the parent-child interaction in free play and in the strange situation (Ainsworth and Bell 1970). The revised practice parameter also includes an outline for a possible clinical observational assessment of attachment that may be used in the evaluation of children with RAD/DSED (Zeanah et al. 2016).

Treatment

The most important intervention for children with RAD and DSED is to provide the child with emotionally available attachment figures. Unfortunately, adoption by a healthy, good-enough new family is not always possible. However, two alternative strategies toward achieving this goal were reported to effectively improve signs of RAD in institutionalized children. The first approach includes changes and interventions within institutions, and the other includes placement of the

children into foster care, accompanied with supervision and guidance for the caregivers.

It has been demonstrated in two studies that within-institution changes and interventions can result in significant improvement of attachment disorders. In one study by McCall and colleagues (as reviewed in Zeanah and Smyke 2008), an intervention designed to change the quality of institutional caregiving was conducted. Two interventions were implemented: staff training focused on more sensitive caregiving as well as structural changes to decrease the number of caregivers per child. Three institutions were included in the study: in one, both staff training and structural changes were implemented; in a second, only staff training was provided; and in the third, no intervention was implemented. Results indicated that children whose institution received the two interventions displayed substantially more proximity-seeking and contact-maintaining attachment behavior and less avoidant attachment behavior with their caregivers compared to children in the other two groups.

Smyke et al. (2002) conducted a similar interventional study in an institution in Romania. Usually, in these institutions, the staff turnover is high and children have many different caregivers during the week. In the “pilot” units, structural changes were made in order to reduce the number of caregivers working with each child, without changing the overall number of caregivers. The researchers examined signs of RAD and DSED in children receiving the “standard care” versus children on a “pilot” unit as well as children living with their parents and attending childcare facilities. Smyke et al. reported significant differences among the groups, with consistently more signs of both RAD and DSED in children on the standard unit. Interestingly, the staff’s behavior on the “pilot” units changed as well in that the staff demonstrated more personalized and affective attitudes and was more psychologically invested in the children in their group compared to caregivers on the standard care unit. This suggests that focusing caregivers on a specific group of children may have positive effects on both caregivers and children.

As abovementioned, a randomized controlled trial study of foster care as an alternative to institutional care was implemented in the Bucharest Early Intervention Project (Zeanah et al. 2003). This project included 136 children with half of the children randomly assigned to foster care and 68 children to continued institutional care. The children were followed longitudinally through 54 months of age. Seventy-two family-reared children recruited from pediatric clinics in Bucharest were also included in the study as a comparison group. Local foster parents were recruited through advertisement and were trained using a manual that had been developed by Romanians and for Romanians. Three project social workers were trained to provide a variety of services to foster parents and the children they cared for, focusing on the needs of the children for stable, consistent, and emotionally available caregivers. The aim was to have the foster parent become emotionally invested in the child as if he or she was their own child. Results of this study indicated that signs of RAD were reduced substantially by placement in foster care, and the response to placement was early and sustained. Over time, the symptoms of RAD in the foster care group became indistinguishable from those in the community comparison group. However, signs of DSED responded to placement more modestly.

Most of the studies and documentations of RAD/DSED include children who were institutionalized. In the community or in situations in which there are parents or defined caregivers who can be considered as emotionally available, a systemic approach is needed. Parenting style and its “goodness of fit” with the child’s temperament and needs should be assessed. The recommended treatment will be attachment-based therapy, aiming to enhance positive child-caregiver interactions and to coach and teach the caregiver to reflect on the child’s feelings and needs and to respond sensitively. Dyadic therapy with the caregiver and child together is recommended as well, if possible. A family-based wider approach that involves other family members can enhance and broaden the positive achievements accomplished in dyadic therapy. Additional interventions

targeting comorbid conditions as behavioral difficulties and developmental and language delays are also recommended (Zeanah et al. 2016).

Basically, individual therapy with the child without collaboration with the caregivers is insufficient for the treatment of RAD/DSED (Boris and Zeanah 2005). It has been clearly stated by the American Psychiatric Association and the AACAP that nontraditional coercive treatments, based on noncontingent physical restraint or coercion (“holding,” “rebirthing therapy,” and more), do not have any empirical support and have been associated with serious harm and even death. Therefore, these treatments for children with RAD, DSED, or other attachment or behavioral disorders are contraindicated or even considered to be maltreatment (Boris and Zeanah 2005; Chaffin et al. 2006; Zeanah et al. 2016).

There is no specific pharmacological treatment for RAD. Psychopharmacologic agents may be used to address secondary difficulties and problems such as hyperactivity and difficulty focusing or sleeping but are not indicated for the core features of RAD or DSED.

Readiness to Learn

► Optimal Arousal

Reading

Diana B. Newman

Communication Disorders Department, Southern Connecticut State University, New Haven, CT, USA

Definition

Reading is a complex skill by which one extracts meaning from print. Reading research has identified successful understanding of what is read or reading comprehension, as largely requiring two fundamental skills: decoding (i.e., word recognition) and language comprehension. Referred to as the simple view of reading by Gough and Tunmer (1986), reading comprehension is considered to be the product of decoding and language comprehension. If either or both of these skills are weak, text comprehension suffers; that is, neither alone is sufficient to support reading comprehension. The success of reading comprehension is further determined by the coordination of these two components so that the process is automatic and accurate (i.e., fluent) (Scarborough 2001).

Historical Background

Over the last century, our understanding of reading has developed from a narrow view to one that recognizes the numerous factors that converge in reading. Early in the twentieth century, reading was thought to be simply the oral recitation of printed words; the ability to read was discussed in terms of systematic phonics, while little attention was given to comprehension skills. A few years later, a shift in educational pedagogy occurred in which learning to read by knowing

the sounds associated with letters (phonics) transitioned into expectations for whole-word reading (sight words); yet there still was little attention to reading as more than that. Approaching the middle of the twentieth century, it became more apparent to educators that reading development required knowledge beyond word reading alone, such as language, experience, attention, vocabulary, thinking, and even instruction. Today, it is agreed that reading requires being actively engaged in the convergence of processes such as phonological awareness (i.e., the ability to recognize and manipulate the sounds in words), memory, and retrieval with language and comprehension strategies.

Current Knowledge

Reading Components

Reading is a process that requires decoding and language comprehension with a degree of fluency. With instruction, practice, and motivation, the typical learner builds skills upon skills, gradually moving toward being an independent, proficient reader of multiple genres.

Decoding

Decoding is the ability to read words, including both real and nonsense words. It requires the application of knowledge of letter-sound relationships (i.e., phonics), including knowledge of letter patterns (i.e., orthography). Decoding skills account for most of the success in comprehension skills, especially in learning to read and early reading. Phonological processing skills account for most of the development of decoding skills. Phonological processing skills include phonological awareness, phonological memory, and phonological retrieval (naming). Phonological awareness is the ability to recognize that words are made of sounds (analysis) and to be able to manipulate those sounds in tasks such as rhyming words and blending sounds into words (synthesis). Translating the letters of a printed word into corresponding sounds (phonological codes) that are then stored with meaning in

memory is referred to as phonological memory. Phonological naming is the quick retrieval of these phonological codes from permanent memory, for example, names of common objects, colors, digits, or letters. When reading, efficient retrieval of phonological codes associated with letters, word segments, and whole words affects the success with which phonological information may be used in decoding (Wagner et al. 1997).

At about the same time that a child develops early phonological awareness skills, the alphabetic principle is recognized, that is, letter-sound associations are learned (i.e., phonics). With instruction and practice, a sight word bank is then developed using phonological memory, that is, coding information (making letter to sound associations) for temporary storage of that information so that the reader maintains an accurate representation of the phonemes associated with letters or parts of words while devoting cognitive resources to ongoing decoding and comprehension processes (Wagner et al. 1997). Sight words then are not words that are memorized through visual skills but instead are words that have been rooted in memory through initial decoding (analyzing the letters and attaching sounds to those letters) (Ehri 1995). Thus, in sight word reading, the words are not read by sounding out letters but instead have been anchored to their pronunciation in memory so they are quickly and accurately read (i.e., retrieved from memory) (Ehri 1998).

Well-developed knowledge of phonics enables the reader to decode unfamiliar words, thus ever increasing the store of available sight words. Children move through phases of sight word learning: prealphabetic phase in which a word is recognized by purely visual cues, partial alphabetic phase in which a word is accessed by remembering letter-sound associations of salient letters in that word, full alphabetic phase in which all letters and sounds are matched in a word, and consolidated alphabetic phase in which multi-letter patterns (e.g., “igh”) are also matched.

Decoding skills should be measured in tasks that require reading both real and nonsense words; however, measuring the ability to read nonsense

words provides a truer assessment of phonological skills and phonics because the meaning/recognition of words is removed. Decoding must not only be accurate but also automatic. That is, letter-sound associations must be quick. Oral reading of word lists and connected passages allows for insight in a student's word identification strategies and degree of fluency. Through oral reading, for example, the student may become aware of word reading problems and seek to correct any errors using phonological awareness and/or phonics skills.

Language Comprehension

Language comprehension or the ability to construct meaning from words whether spoken or written requires two kinds of knowledge: linguistic knowledge and background knowledge, each is somewhat dependent on the other. Linguistic knowledge is the knowledge of the formal structures of a language, while background knowledge is the knowledge of the world, including content and procedural knowledge acquired through exchanges with one's surroundings. Together, these knowledge bases enable one to draw inferences, thus allowing for interpretations beyond the literal.

Linguistic knowledge may be described as an understanding of those domains upon which competency in a language depends: phonology, semantics, and syntax. Phonology is defined as the sound structure of a language, semantics as the meaning component of a language (words and their meaningful parts, i.e., vocabulary), and syntax being the rules of language that dictate how to combine words to form sentences.

Differently, background knowledge is the understanding of how events work based on prior interactions with the environment; this background knowledge provides for the development of schemata. A schema is a structure that one uses both to organize current knowledge and to understand new information and experiences. In communicating through language, a well-developed schema in a particular domain of knowledge allows for understanding of even new information relevant to that domain because there is already a meaningful structure in place for interpreting the information.

Reading comprehension requires making sense of the printed words that have been translated into language (decoding). That is, reading comprehension requires language comprehension to draw upon both linguistic information and background knowledge so that in reading one may go beyond what is explicitly stated, link up ideas within the text, and derive meaning from what has been read. Of final importance though is that comprehension of print also requires literacy knowledge, that is, a familiarity with story structures and genres (Scarborough 2001).

Language comprehension is classically measured through oral language tasks. These include but are not limited to measures of receptive vocabulary, grammatical understanding, and discourse comprehension. Specific to the last, it is often suggested that this be assessed by a listening comprehension task using age-appropriate passages from an informal reading inventory. After listening to spoken passages, the student is asked questions targeting both information that was explicitly presented in the passage and that which was only inferred to in the passage.

Fluency

Although reading comprehension is determined largely by abilities in decoding and language comprehension, fluency is also a necessary component. That is, once a child can decode and has the necessary language skills, fluency should follow. To be fluent means decoding is fast and accurate (i.e., automatic), and reading is delivered with appropriate intonation. Fluency may be compromised in one or several ways. An individual may be fast but inaccurate. Occasional errors are realistic (at 99% accuracy, one is considered to be at an independent level, 95–98% instructional reading level). Although errors are acceptable even for fluent reader, too many errors if not caused by an attentional difficulty are typically caused by a lack of automaticity in decoding. Lack of automaticity in decoding may be due to a lack of skills in phonological awareness (e.g., a difficulty blending sounds even if one knows the letter-sound associations) or a lack of letter-sound knowledge (what sound does/g/make). An

individual can be slow but accurate. In terms of rate, for example, at the end of first grade, a child is in the 50th percentile if orally reading 53 correct words per minute; at the end of eighth grade, a student is in the 50th percentile if orally reading at 151 words per minute (Hasbrouck and Tindal 2006). Finally, an individual can be both slow and inaccurate. Particular to inflection and prosody, matching the stress and intonation of the text reflects correct on-line monitoring of what is being read, for example, use of a sad tone spoken by the character or a rising cadence as a reaction of the reader to a surprising statement.

Stages of Reading

Reading is a multifaceted process and as such requires systematic, organized instruction in the development of each of the stages of reading (Chall 1996): Stage 0 is referred to as the pre-reading stage, stage 1 as the initial reading or decoding stage, stage 2 as the confirmation stage, stage 3 as the reading for learning the new stage, stage 4 as multiple viewpoints stage, and stage 5 as the construction and reconstruction stage.

Beginning with stage 1, the stages of reading may be divided into those in which the child is learning to read and those in which the child is reading to learn. In learning to read, the characteristics of children reading in stages 1 and 2 (typically seen in grades 1, 2, and 3) include the ability to read simple, familiar texts and use the alphabetic principle to decode unfamiliar words. Differently beginning at stage 3 (typically grades 4–8), texts contain new words and ideas beyond the child's linguistic and background knowledge; therefore, there must be fluency in word recognition and critical thinking outside the child's knowledge. The transition from stage 2 to 3 is critical for academic success here on. In stage 4 (typically high school), students are expected to use strategies to be able to see different perspectives and to work with additional layers of facts and concepts beyond what was learned earlier. Reading in stage 5 (typically college) demands the construction of meaning at a high level of abstraction, integrating information across settings with a purpose.

Reading Disabilities

The simple view of reading suggests not only a way of defining reading ability but may also be used to classify a reading disability (Catts et al. 2006). The simple view presumes that once the printed matter is decoded, the reader applies to the text exactly the same mechanisms (linguistic knowledge and background knowledge) that would be used on its spoken equivalent. Gough, Hoover, and Peterson (1996) suggest that beyond the point of word recognition, both listening and reading appear to require essentially the same processes.

Using the simple view as a framework for classification of reading and reading disabilities, four types of readers emerge when decoding and language comprehension are measured:

1. Good readers or those with good decoding and good language comprehension
2. Dyslexic readers or those manifesting only a decoding difficulty
3. Poor comprehenders (or at the extreme, hyperlexic readers) or those exhibiting only a language comprehension difficulty
4. Mixed deficit poor readers or those demonstrating difficulties in both decoding and language comprehension

The use of this classification system which is based on the two fundamental components of reading has direct implications for both assessment and subsequently intervention. That is, effective intervention must be preceded by assessment of both decoding and language comprehension, neither of these should be assumed to be fully developed despite the age of the child. Then intervention focusing on improving specific areas of need, decoding and/or language comprehension should be carried out.

Heterogeneous Nature of Reading in Autism

There is a general belief that reading is a relative strength for individuals with autism spectrum disorders (ASD) (Nation et al. 2006). This assumption is based upon research and clinical observations which have reported many of those with ASD to have the ability to accurately read

aloud single words presented out of context; sometimes this ability is even beyond that expected by IQ. However, reading is not only this single process of word recognition but instead is the integration of two processes, decoding (which allows for word recognition and word identification) and language comprehension (Gough and Tunmer 1986). For many individuals with ASD, there is a disassociation between the two constructs of reading, decoding and language comprehension. This is because many of these individuals have language impairments, thus even with good word reading skills, their reading comprehension is poor.

Decoding in Individuals with ASD

Despite the notion that decoding is a relative strength in individuals with ASD, there is much variability in decoding accuracy. Decoding ability is measured by both word and nonword reading accuracy. Studies have found individuals with ASD to be able to read both real words and nonsense words, the first reflecting good word recognition, the latter, good underlying phonological skills. Yet it has also been found that some individuals with ASD, though relatively skilled at reading real words, are quite poor at reading nonsense words, perhaps considerably lower than the level expected given their ability in real word reading. This discrepancy suggests their real word reading is based on a visual strength (rote visual memory or association) as they lack the phonological skills (“sounding out” using letter-sound associations) to read nonwords. (Note that phonological skills are part of typical reading development.) Finally, there are those with ASD who do not evidence adequate measureable single word reading, either real or nonwords. Thus, within the population of individuals with ASD, some read both real words and nonwords accurately, some read real words but are unable to decode nonwords, and others are poor at both real and nonwords.

In discussing word reading accuracy, it is important to include mention of hyperlexia. Hyperlexia is a reading profile in which there is exceptionally well-developed word reading yet very poor reading comprehension in individuals

with marked cognitive and linguistic deficits; an early onset of preoccupation with reading is also evident. Strong skills in reading nonsense words as well as real words suggest that individuals with hyperlexia use phonological decoding strategies as typical readers do, and do not rely on visual memory or whole-word recognition (Newman et al. 2007). Yet despite this remarkable word reading, these individuals have significant difficulty understanding connected language (read or heard); thus, hyperlexia is a disorder of comprehension. In fact, though reading fluency in those with hyperlexia has been found to be excellent despite content, when it becomes necessary to stop and comprehend, fluency significantly decreases (Newman et al. 2007). As these reading, cognitive, and oral language characteristics tend to come together in individuals with autism, patterns of hyperlexic reading are therefore more frequent in this group (Nation et al. 2006).

Language Comprehension in Individuals with ASD

Despite adequate levels of word reading accuracy (i.e., decoding) in the population of individuals with ASD as a whole, poor reading comprehension is typical. Therefore, in keeping in mind the two components of reading, decoding (i.e., word reading) and language comprehension, it is the latter with which this population most often struggles. Specifically, impairments in vocabulary and oral language comprehension are typically measured and thus are associated with reading comprehension difficulties. However, as is the case with decoding, language abilities and difficulties vary in the population. There may be, for example, a general difficulty with integrating information read, difficulty understanding anaphoric references (linking pronouns to their antecedent nouns in the text), difficulty with using prior knowledge to make connections with new information read or difficulty with comprehension monitoring (Nation et al. 2006). Further, there may be a discrepancy between understanding explicit (i.e., literal) versus implicit (inferential) information: For those with ASD, the former being easier than the latter (a higher-level language skill). Additionally, difficult to comprehend

are words with multiple meanings figurative language, humor, as well as characters' motives, their goals, and their internal states (e.g., emotions).

Importantly, however, despite the large number of individuals with ASD who have relative strengths in word recognition and therefore reading comprehension difficulties stemming only from language difficulties, there are individuals with ASD for whom impairment in reading comprehension is due not only to language comprehension weaknesses but also, at least in part, to poor word reading accuracy. That is, these individuals are unable to recognize or decode the written word.

Reading Fluency in Children with ASD

As in typically developing children, the oral reading of those with ASD will vary as a function of word reading skills (decoding). That is, accuracy and rate will fall in line with decoding skills. However, for those with ASD, expression may be poor. Reading may lack appropriate pauses, changes in tone that reflect emotions of the characters, and/or necessary emphasis of words critical to meaning of the text. These deficits are thought to be associated with the more general deficits of social skills and pragmatic language development which are characteristic of ASD (Henry 2010).

Reading Assessment and Intervention in Children with ASD

Given that reading is primarily the product of decoding and language comprehension, assessment must comprehensively investigate each of these factors, that is, identifying both strengths and weaknesses in each area. Criterion-referenced instruments along with, as appropriate, standardized tests should be used to measure a learner's reading patterns.

Decoding refers to the word recognition processes that analyze the letters of a written word, transforming print to pronunciation of that word. Processes such as phonological awareness and knowledge of letter-sound associations (referred to as the alphabetic principle) are necessary for decoding unfamiliar words. Careful identification of decoding skills of the learner establishes areas

of need and sets the baseline for intervention in word reading.

However, good performance in decoding does not guarantee adequate reading comprehension. Especially when supporting those with ASD, dependence on assessments of word reading alone may overestimate reading comprehension as a strength. Autism and language are well connected, and language comprehension is necessary for reading; further, oral language abilities and reading development of students with ASD have been found to have a bidirectional relationship (i.e., improvement in one improves the other) (Lanter and Watson 2008). Therefore, the assessment of the learner's oral language skills using criterion-referenced instruments along with, as appropriate, standardized tests is necessary even if the individual has adequate or extraordinary single word reading (decoding). Keeping in mind that responses to comprehension questions should reflect the reader's relationship with the text, assessment and instruction should include not only answering literal questions (facts from the passage read) but questions that encourage inferencing, connecting prior knowledge with the author's meaning, and interpreting meaning.

Converging research has identified areas associated with reading achievement. These areas are decoding including phonological awareness, reading fluency, language, and comprehension strategies. Reading is not a single construct, and in those with ASD, reading components usually have dissociated. General reading instruction and intervention recommendations for children with ASD cannot be made; instead given the heterogeneous nature of reading skills in learners with ASD, individualized reading assessments should lead to appropriate reading instruction. It can be said, however, that best practice in reading instruction for children with ASD includes the use of rich and meaningful contextualized examples presented multiple times.

Future Directions

The National Reading Panel (2000) summarizes the future direction of reading as follows: Though

the literature in reading research is significant and converges into several key areas (e.g., phonological awareness is necessary for decoding), the need for continued research using rigorous experimental or quasi-experimental design that investigates reading instruction is clear if reading education is not to fall prey to educational fads. Additionally, today, technology is changing education. Research into its use as a tool in the teaching and learning of reading has been limited thus far and in much need.

Reading Comprehension Impairments in School-Aged Children with HFA

Nancy S. McIntyre
Frank Porter Graham Child Development
Institute, University of North Carolina, Chapel
Hill, NC, USA

Definition

Children and adolescents with autism spectrum disorder (ASD) who are not affected by intellectual disability (ID) are often referred to as having higher-functioning autism (HFA). Many of these students spend substantial portions of their school day in general education settings where the ability to competently read, comprehend, and use written texts is critical for accessing the core curriculum

in science, social studies, language arts, and, increasingly, mathematics. Reading comprehension is a foundational learning mechanism and is intertwined with all literacy skills, including critical thinking, writing, listening, and following directions. Furthermore, reading can provide a portal into fictional worlds where relationships, emotions, and adventures are detailed and available for consumption at one's own pace and for rereading as often as desired. Therefore, developing proficient reading comprehension skills should be an essential goal for students with HFA.

Historical Background

Comprehending what one reads requires coordinated and efficient processing of many key components. The Simple View of Reading (SVR; Gough and Tunmer 1986) is a commonly used framework to explain the separate skills that underlie reading comprehension. According to this model, word recognition skills (decoding and sight word reading) and listening comprehension skills both make independent, and necessary, contributions to proficient reading comprehension. If a reader struggles with either of these main components, they will have difficulty accessing written texts. Developmentally, reading for meaning progresses over time and builds upon two key abilities already present in infancy: the ability to visually recognize objects and oral language skills. By the time children are 5 or 6 years old and entering elementary school, key visual recognition processes are well developed and most have expert oral language knowledge of phonology (sounds of language), basic grammar rules, and a vocabulary of several thousand words. As children learn to read, they develop letter-sound correspondence by connecting the sounds they hear in spoken language to the visual symbols, or letters, that represent them and apply that to decoding new words, progressing from the simple to the complex. Over time newly acquired words are stored in memory, and the pathway used to identify words by sight develops and progressively supplements the decoding pathway. Oral language processing creates meaning from the

words. These two processes may develop relatively independently, and the relationship between these factors and reading comprehension changes over time. For younger children decoding is more important because it is not yet automatic, but by secondary school decoding differences are generally small, and the relationship between reading and listening comprehension is very strong. Therefore, one should expect a person's reading comprehension to develop to the same level as their listening comprehension once word reading is fluent (Cain and Oakhill 2008). The SVR and the manner in which the skills develop over time will provide a framework for understanding reading comprehension challenges for students with HFA.

It is concerning that research has identified high rates of reading comprehension impairments in children and adolescents with HFA that are not consistent with their overall cognitive abilities (e.g., Jones et al. 2009; McIntyre et al. 2017). This learning difficulty not only affects current academic development; it also impacts future vocational outcomes such as full-time employment and earnings prospects and has been shown to predict earnings of workers across educational attainment levels and occupations. Impairments in comprehension skills can limit the ability to learn new information and communicate effectively, thereby further impacting independent living capacity in adulthood. Therefore, understanding and addressing the high rates of reading comprehension impairments in school-aged children and adolescents with HFA is an important endeavor.

Current Knowledge

The SVR framework supplies a foundation upon which to build an understanding of the general reading challenges that students with HFA may share with all students who struggle with reading. However, there is some evidence to suggest that in addition to the broad constructs of word recognition and listening comprehension, the comprehension difficulties experienced by many students with HFA may also be specific to their social communication and cognitive characteristics.

General Reading Challenges

Word recognition skill is dependent upon oral language skills such as phonological processing of speech sounds for word decoding and vocabulary development (National Reading Panel 2000). For many students with HFA, decoding skills develop adequately and word reading is a relative strength upon which to build. However, some do experience difficulties developing proficient word recognition skills, and those challenges are linked to phonological processing impairments similar to readers without ASD (Åsberg and Dahlgren Sandberg 2012). Of note, the word recognition impairments of readers with ASD have also been shown to be related to challenges in key aspects of oral language such as morphology (i.e., smallest parts of words that convey meaning such as prefixes and suffixes), syntax (i.e., word order in sentences), and vocabulary (Ricketts et al. 2013). This is important because oral language skills often develop atypically in children with ASD who display a wide variety of expressive and receptive language abilities that may develop at different rates and to different levels of competence (Eigsti et al. 2011). Therefore, the link between these language skills and word recognition is important to recognize, assess, and apply when targeting reading intervention services.

Listening comprehension skills such as narrative abilities and inference generation have been shown to be challenging for typically developing readers with poor comprehension (Cain and Oakhill 2008) and also for readers with HFA (McIntyre et al. 2017). In early elementary school, children are primarily exposed to academic and narrative content through read-alouds and oral discussions lead by caregivers and teachers. Listening comprehension skills develop in these contexts and should not only include an understanding of the individual words and sentences but also should lead to the construction of a mental model of the presented information that integrates one's related background knowledge. When the content is narrative in nature,

comprehension relies on understanding and utilizing story structure, the social-cognitive ability to understand the intentions and beliefs of characters in a story, as well as language skills more broadly, and research findings support a causal relation between narrative skills and reading comprehension development (Cain and Oakhill 2008). Children with ASD often display difficulties with narratives which may be due to difficulties with social cognition and oral language skills (Randi et al. 2010). Regardless of content area, the ability to generate links between different pieces of information as well as to connect to, and integrate, what one already knows about a topic is known as inference generation. Making inferences allows a listener or reader to fill in gaps and resolve ambiguities about what they are reading or hearing to attain deeper comprehension. Answering comprehension questions that require inferential thinking is much more challenging for most people than answering questions that depend on direct recall of facts and details, and research has reported that students with HFA have a relative strength for correctly answering direct recall questions (McIntyre et al. 2017). This could be the case because individuals with ASD may have difficulty accessing relevant background knowledge and integrating it with information in texts to make inferences, particularly when the content is highly social (Norbury and Nation 2011). Oral language skills have also been linked to inferential processing, and while individuals with ASD who have well-developed verbal skills have not displayed an overall problem with inference, they have demonstrated a particular difficulty with inferences about social and emotional information (Bodner et al. 2015; Happé 1995).

Finally, while both word recognition and listening comprehension skills are related to reading comprehension in readers with HFA, research has shown that they are not as tightly associated in students with ASD as they are in other groups of students (Jones et al. 2009; McIntyre et al. 2017). This is likely due to a higher incidence of a reading profile characterized by adequate word recognition skills alongside poor comprehension in many children

and adolescents with HFA, which is notable and likely specific to the language and greater social communication challenges in readers with ASD.

ASD-Specific Challenges

Beyond the components of the SVR, characteristics associated with a diagnosis of ASD impact reading comprehension for many students with HFA. Social communication, or the ability to use language and nonverbal communication in a purposeful way to convey a message to another person, plays a role in understanding that written texts are a form of communication with an intended meaning or purpose and are subject to different interpretations by different people. Specifically, the ability to attribute mental states such as desires and motivations to oneself, and to infer others' mental states, plays a key role in understanding and predicting their behavior and is often referred to as theory of mind (ToM). ToM helps one to understand that the purpose of oral and written language is to express thoughts and feelings and to aid in the interpretation of a speaker or writer's intended meaning. Not only is this relevant for texts read in school settings, it is increasingly important as computer access to social media, online forums, and news websites proliferates. Readers need to be able to discern the differing perspectives and motives of the online authors not only for accurate comprehension but also for their safety and well-being. For example, not understanding someone's intentions could lead to becoming the victim of fraud or becoming misled and upset by exaggerated viewpoints. ToM tasks have been shown to predict narrative text comprehension in all readers likely because the tasks capture inference making and complex social reasoning skills that are necessary for understanding characters' intentions and beliefs (Kim 2015). Impairments in ToM are reported across developmental stages and functioning levels in individuals with ASD (Baron-Cohen et al. 1997) and oral language skills have been linked to performance on ToM tasks (Happé 1995). Highly social texts have been shown to be more difficult to comprehend than those with

lower social content for children with ASD (Brown et al. 2013), and impairments in ToM explain differences in reading comprehension for children and adolescents with ASD that extend beyond the contributions of word recognition and listening comprehension skills (McIntyre et al. 2018; Ricketts et al. 2013). Taken together, there is growing evidence that comprehension challenges may also align with ASD-specific social-cognitive vulnerabilities.

A cognitive characteristic associated with ASD, restricted interests, can limit the breadth of background knowledge in long-term memory that is available for inference-making since an extensive focus on one or two topic areas diverts attention from broader learning experiences. Even when an individual has access to an extensive variety of experiences, a lack of interest or engagement may limit their uptake and benefit from these opportunities. Not only will this impact their general knowledge fund, it also affects their language and social development which in turn impacts reading comprehension. A related issue is inflexible and concrete learning seen in many students with ASD that may limit their ability to generalize and apply knowledge or skills learned in one context to new situations or settings. Readers with HFA might not realize when they have background knowledge that is relevant to a text, or fail to suppress irrelevant knowledge, and therefore miss opportunities for deeper comprehension. Another aspect of cognitive processing that is associated with, although not exclusive to, ASD is a tendency to focus on details rather than global meaning, which is often referred to as weak central coherence. This can impact reading comprehension because a focus on details leads to difficulty perceiving the larger meaning of a text which in turn leads to difficulty identifying main ideas and themes and integrating text meaning with background knowledge. This processing style also makes it more difficult to generalize and apply ideas and concepts to other texts. This becomes increasingly important in middle and high school when students are asked to do things such as extract themes from novels and compare or contrast them across other novels or

situations. If one is not able to identify global meanings and greater themes, it is difficult to recognize similarities between texts. Taken together, reduced breadth of background knowledge, contextualized learning, and a tendency to focus on text details rather than central meaning lead to difficulties building a comprehensive mental model of the text.

Building Reading Comprehension Skills

A body of reading comprehension intervention research with elementary through high school students with ASD is emerging. Specific intervention strategies and methods that have demonstrated promise include question generation (teaching students how to ask relevant questions about a text to facilitate monitoring and repair of comprehension), pronoun identification (determining the person or object to which the pronoun is referring), explicit or direct instruction techniques, making predictions about a text, cooperative learning groups, and peer tutoring. The use of visual supports in the form of graphic organizers, story element and word cards, and self-monitoring checklists has shown promise as well (El Zein et al. 2014). Teaching students to generalize text comprehension strategies outside the intervention materials to other texts is also an important intervention ingredient. Use of multiple exemplars while teaching, graphic organizers such as Venn diagrams, response-prompting strategies, cooperative learning instruction with typically developing peers, and computer-aided instruction all have shown some promise in promoting generalization across materials and exemplars for students with ASD (Sartini et al. 2018).

To expand on one instructional practice noted in both research reviews, reading interventions that also include a peer-mediated social component such as cooperative learning groups or peer tutoring can promote more active student engagement and increased opportunities to communicate and collaborate. Research on school-based peer-mediated interventions for children and adolescents with ASD has demonstrated that they are a promising approach to improving social competence along with academic functioning and access

to the general education curriculum for students with ASD (Bene et al. 2014; Ledford and Wehby 2015). A small body of prior research has demonstrated positive effects of peer-mediated reading comprehension interventions on both reading and social outcomes simultaneously for children and adolescents with ASD (Bene et al. 2014). Interventions of this type offer the possibility of a targeted approach to intervention for academic achievement that fits well with the curriculum and expertise of general education classrooms and may have a cascading positive impact on the social communication development of school-aged children with ASD.

Future Directions

While evidence is emerging in support of specific strategies or instructional practices, little is known about intervening comprehensively on challenges in oral language, global processing, social cognition (ToM), integration of background knowledge and inference making, and generalization to other texts and across contexts that may be specific to the social and cognitive characteristics of ASD. Neither do we know which of these skills are the most crucial to include in comprehensive reading instruction for students with HFA that are effective for varying age groups. Additionally, little work has been done with samples of students with HFA to examine other cognitive processing domains related to reading such as self-monitoring of comprehension and engaging in repair strategies, planning and organization, attention, inhibition of irrelevant information, memory, and how impairment in these skills impacts their text comprehension specifically. Finally, more research on academic achievement and reading instruction for individuals with HFA in the elementary and secondary grades that emphasizes the relationship between social and academic skills and simultaneously addresses both skill areas is warranted. As with other students, students with HFA have a variety of strengths and weaknesses that call for an individualized and flexible instructional approach. Therefore, a

curriculum that addresses multiple areas of concern (e.g., reading and social communication) and is adaptable may be the most feasible and effective for teachers to implement in general education settings and may ultimately serve the needs of many students in these settings with reading comprehension challenges.

Reading Comprehension Strategies in Autism

[Reading interventions](#)

Definition

Individuals with autism spectrum disorders (ASD) have significant variability of academic skills. For example, some students with autism may have age-appropriate decoding skills, but lack reading comprehension skills, while some students with ASD have deficits in both decoding and comprehension. Language, vocabulary, and decoding issues can all play a role in the lack of ability to understand text. In addition to these concerns, individuals with ASD also have impairments in three areas of cognition: theory of mind (Baron-Cohen 1995), central coherence (Frith 1989), and executive functioning (Luria 1966). Challenges in these areas can also impact their reading comprehension (Carnahan et al. 2011). Teachers can use the following strategies to target these areas of cognition and help support students with ASD when comprehending text.

Strategies to Support Theory of Mind

Theory of mind is the ability to see something from someone else's perspective (Baron-Cohen 1995). Individuals with ASD have a difficult time understanding perspective in social situations; additionally, they may have difficulty understanding perspectives of different characters in texts. This leads to a variety of implications with comprehending text (i.e., making

predictions, understanding emotions, understanding deception, determining fact from fiction, etc.)

This difficulty with perspective taking can be partly attributed to the students' inability to produce and understand pronouns (Finnegan and Accardo 2018). Anaphoric cueing teaches strategies on how to interpret pronouns by connecting pronoun references to specific characters in text. Teachers should target the visual area of strength for students with ASD by highlighting pronouns and character reference in the same color to assist in comprehension. Teachers should then use follow-up questions using pronouns to check for understanding. Supports and questioning can be faded over time.

Strategies to Support Central Coherence

Central coherence is the tendency to draw together diverse information to construct higher-level meaning in context (Frith 1989). Individuals with ASD have difficulty understanding the "big picture" in real-world situations, and they have the same difficulty when reading text. This can impact a student in the ability to identify the main idea and draw conclusions about what they have read.

Developing the schema for the students can help them generate prior knowledge about what they will be reading about. For example, before reading a text about a rainforest, show them pictures and videos about the rainforest and then visually brainstorm thoughts, questions, and facts about what they saw. They may also have an idiosyncratic focus of attention, difficulty making choices, and seeing connections within and across text. Teaching students to record important facts on post-it notes during reading can help students focus in on salient features in a visual way.

Strategies to Support Executive Functioning

Executive functioning skills relate to the ability to maintain an appropriate problem-solving set for attainment of a future goal (Luria 1966).

Individuals with ASD have impaired executive functioning skills and therefore may have difficulty with the following comprehension skills: organizing information within text, focusing on significant events in a story, and understanding alternate facts/opinions. Individuals with ASD often have rigidity in thinking which may lead to an inability to explore the topic by integrating new information, thoughts, or ideas. The use of graphic organizers will help students visually identify and organize what they have read (Finnegan and Accardo 2018). Graphic organizers depicting story elements are a way to target the visual strength of an individual with ASD while providing an organizational tool to target important text features (i.e., characters, setting, problem, solution, etc.).

Reading Skills

Michelle Lestrud

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Reading skills lead a person to interact and gain meaning from written language. There are several components one must master which lead to independently comprehending the intended message being relayed in the written content. First is phonemic awareness which is defined by the National Reading Panel as “recognizing and manipulating spoken words in language” (Whalon et al. 2009). Next is phonics defined by the same group as “understanding letter-sound correspondences in reading and spelling” then oral reading fluency which is “reading text with speed, accuracy, and expression.” The forth component is vocabulary defined as “understanding words read by linking the word to oral vocabulary” and lastly is comprehension defined as “directly teaching students to be aware of the cognitive processes involved in reading” (p. 4).

Typically developing children will start to acquire reading skills in preschool and continue to learn along a continuum until they reach an independent reading level. Students with ASD often acquire some reading skills in an uneven nature which may be indicative of the student’s language delays or rote memory skills. Despite strong decoding skills, students with ASD often have great difficulty becoming skilled readers which requires higher level skills such as making inferences from the text (Lanter and Watson 2008).

Historical Background

Since the early 1900s, theorists have acknowledged that reading is a complex task which requires a number of mastered skills. In 1985, the National Academy of Education held onto

Reading Interventions

- [Reading Comprehension Strategies in Autism](#)

the view supported by Gates in 1949 that reading is complex and requires a number of higher level skills to be manipulated together to achieve reading competence (Gough and Hoover 1990).

A differing view has developed, often referred to as the *Simple View of Reading*, and states “one central claim of the simple view is that reading only consists of two components, decoding and linguistic comprehension (Gough and Hoover 1990).

Current Knowledge

Research has proven that reading skills are acquired through systematic instruction and improve with practice and repeated instruction. Students with autism are a heterogeneous group which means one intervention cannot be prescribed to teach all students. Through reading assessments, an accurate profile of the student’s reading level can be determined and lead to appropriate reading interventions.

Future Directions

Research needs to continue in the area of developing reading skills for children with ASD. Whalon, Otaiba, and Delano recommend that researchers “evaluate the impact of comprehensive reading instruction on the reading development of children with ASD” (2009). As technology continued to evolve, its effectiveness along with computer-aided instruction should be evaluated as it applies to reading skills of all levels.

²Yale Child Study Center, New Haven, CT, USA

Synonyms

[Eyes Test](#); [RMET](#)

Description of the Instrument

The Reading the Mind in the Eyes Test (RMET) measures theory of mind or how well individuals can put themselves into the mind of another

person and attribute mental states to another person. The test itself takes approximately 20 min to complete and is relatively simple to administer and perform, making it a useful instrument for a variety of populations and settings.

The test consists of a series of 37 photographs of the eye region of the face of different actors and actresses. In addition, the test includes instructions, an eight-page word definitions list, a response form, and an answer form. There is one practice stimulus and 36 experimental stimuli. Each of the 37 images has four response options: emotion words that are defined in the provided word definition list. The response form, which is given to the subject, lists the four response options that are presented with the image. The subject is instructed to circle the word that best describes what the person in the picture is thinking or feeling. Further, the subject is told to choose the word that is most suitable for the image even if more than one word feels applicable. The task is not timed, but the subject is instructed to work as quickly and as accurately as possible.

The score on the RMET is calculated by counting the number of correct responses. While there are no normative data or scores, there are published averages for different populations.

History of the Instrument

The RMET was first developed in 1997 by Simon Baron-Cohen, Ph.D., and colleagues of the University of Cambridge (Baron-Cohen et al. 1997). He and his colleagues developed the test as a means of measuring theory of mind in adults with autism spectrum disorders (ASD). Previous theory of mind tests had been proposed for children with ASD but did not provide an opportunity for insight into theory of mind functioning in adults with ASD. In the seminal paper on the RMET, Baron-Cohen and colleagues (1997) suggested that deficits in theory of mind may underlie some of the difficulties seen in adults with ASD. In this initial study of the RMET, it was found that adults with ASD performed significantly worse (lower total score) than typically developing individuals and individuals with Tourette syndrome (clinical control group).

Further, they found that within the typically developing control sample, females performed significantly better than males; this was not tested in the clinical control group (individuals with Tourette syndrome) or in the experimental group (individuals with ASD). Performance on the task did not correlate with IQ, but all individuals had IQ scores within the average or above average range. This study concluded that theory of mind deficits existed in individuals with ASD, with an average or above average IQ, and that the RMET was successful in accurately measuring these subtle social difficulties. The authors also concluded that the observed theory of mind deficits in these individuals suggested that social cognition is independent of general intelligence (Baron-Cohen et al. 1997).

Since its development in 1997, the RMET has been revised (Baron-Cohen et al. 2001a). The authors identified three major psychometric problems with the first version of the RMET. First, the initial test had only two response options, which limited the range and restricted the interpretation of individual differences. Second, these response options were the basic emotions (happy, sad, anger, fear, and disgust) and were judged to be too easy, leading to ceiling effects. Finally, the two response choices were always semantic opposites; if the subjects were able to judge positive versus negative emotion, they would receive credit without having to utilize theory of mind principles. Thus, major modifications to the RMET appeared in the revised version, which was released in 2001. These modifications included increasing the number of response choices from 2 to 4 words, using only complex mental states as response choices rather than the basic emotions and including foil words that had the same emotional valence as the target word (i.e., target word, serious; foil words, ashamed, bewildered, and alarmed) instead of semantic opposites. It was found that with these modifications, individuals in the typical control group performed below ceiling, indicating that the revised test had more power to discriminate and identify meaningful individual differences. The results of the initial study (Baron-Cohen et al. 1997) were replicated; individuals with ASD were significantly impaired on the revised RMET as well. In addition to the

revised version of the adult RMET, a children's version of the test was also released in 2001 (Baron-Cohen et al. 2001b). The children's version of the RMET is very similar to the adult version; however, the response choices have been changed to be more suitable for children.

Psychometric Data

Normative Data

The RMET does not have normative data, but rather the total raw scores are used to compare between individual and group performance on the task. Baron-Cohen et al. (2001a) reported an expected distribution for typically developing adults, with adults with ASD performing significantly worse (lower total score).

Reliability

The reliability of the RMET has been broadly studied and is generally accepted as good. In a study of the Swedish version of the RMET, a group of students (mean age 23.9 years) completed the test at two time points separated by 3 weeks in order to evaluate test-retest reliability (Hallerbäck et al. 2009). There was no significant difference found between the mean score from time point 1 and time point 2 ($p = .35$). Further, there was a significant positive correlation between the scores from the first and second time points ($r = .60, p < .01$).

Validity

Baron-Cohen et al. (1997) initially reported on the validity of the RMET as a true test of theory of mind based on the idea that it did not involve executive functioning skills nor did it require a central coherence component (Ozonoff et al. 1991; Frith 1989). In order to validate the test, performance on the RMET was compared to performance on Happé's Strange Stories task (a known test of theory of mind) and two control tasks (Gender Recognition task and Basic Emotion Recognition task) (Happé 1994; Baron-Cohen et al. 1997). Individuals with ASD were significantly impaired on both the RMET and Happé's Strange Stories task as compared to a typically developing control group and a clinical

control group (individuals with Tourette syndrome) (Happé 1994; Baron-Cohen et al. 1997). Further, there were no differences between the groups on the either of the control tasks. Finally, Baron-Cohen et al. (1997) reported that because the target words were mental state terms and not just emotion terms, the RMET was testing theory of mind and not emotion recognition. Thus, it was concluded that the RMET was valid and indeed testing theory of mind.

The 2001 revision of the RMET provided direct evidence for the validity of the test (Baron-Cohen et al. 2001a). Results from the original study of the RMET (Baron-Cohen et al. 1997) were replicated in the study of the revised version, suggesting that the RMET is indeed a useful test for detecting individual differences and impairment in theory of mind functioning level in adults. Since its release, the revised version of the RMET has also been used in many studies of a wide range of psychological/neurological conditions. These studies have demonstrated that the RMET can reliably distinguish between nonclinical samples and clinical samples both in behavioral studies and fMRI studies (Baron-Cohen et al. 1999; Lee et al. 2005; Hallerbäck et al. 2009).

Clinical Research Uses

The RMET was initially developed as a behavioral test of theory of mind functioning level in adults with ASD. Since its release in 1997, it has been widely used in behavioral and functional magnetic resonance imaging (fMRI) studies with both children and adults.

The RMET has been instrumental in demonstrating theory of mind impairments associated with a variety of clinical populations including, but not limited to, ASD, depression, schizophrenia, and dementia and Alzheimer's disease. Lee et al. (2005) found that the ability to decode other's mental states was significantly impaired in severely depressed individuals and suggested that strategies that improve theory of mind reasoning may be useful in therapeutic interventions for severely depressed individuals. Furthermore, impaired theory of mind functioning in

individuals with schizophrenia has also been evaluated using the RMET. Bora et al. (2006) assessed mental state decoding in individuals with schizophrenia using the RMET and found that the RMET was successful in predicting level of social functioning. In addition, they determined that mental state decoding seems to be the most important cognitive mediator of social functioning in individuals with schizophrenia. Finally, the RMET has also been used in studies of dementia and Alzheimer's disease. Gregory et al. (2002) found that patients with frontal variant frontotemporal dementia were impaired on the RMET and that individuals with Alzheimer's disease were not significantly impaired. They concluded that theory of mind impairment may explain some of the deficits in interpersonal behavior experienced in frontal variant frontotemporal dementia and not in Alzheimer's disease.

The RMET has also been widely used in fMRI studies of ASD and other psychiatric disorders. Many studies have found that the deficits in theory of mind in individuals with ASD, as measured using the RMET, are substantiated by different brain activation patterns in response to social stimuli (Baron-Cohen et al. 1999; Gordon et al. 2013). Furthermore, Hirao et al. (2008) found that in individuals with schizophrenia, poor performance on the RMET was associated with reduced gray matter in the left ventrolateral prefrontal cortex (VLPFC). Thus, they suggested that this gray matter reduction may be important in understanding theory of mind deficits experienced by individuals with schizophrenia. Finally, clinical effects of oxytocin for individuals with ASD have been evaluated using the RMET. Performance on the RMET was enhanced after intranasal administration of oxytocin in individuals with ASD (Domes et al. 2007; Guastella et al. 2010; Gordon et al. 2013). These findings suggest that oxytocin may be involved in theory of mind deficits associated with ASD (Domes et al. 2007).

Real-Life Rating Scale

Edward Ritvo
UCLA School of Medicine, Los Angeles, CA,
USA

Synonyms

RLRS; Ritvo-Freeman real-life rating scale

Description

The scale is designed to assess changes in symptoms over time in children with autistic disorder. Observers rate rates 47 pathological behaviors on a Likert Scale. It is applicable in natural settings by nonprofessional raters who can be rapidly trained to achieve significant inter observer agreement, is rapid scored by hand, and can be repeated frequently without effecting inter rater agreement. It does not interfere with or alter the behaviors being rated.

Historical Background

The scale was developed by modifying the Behavior Observation Scale (BOS) (Freeman et al. 1996). This standardized instrument utilizes videotape made through a one-way mirror into an observation room in which there is a patient, an observer, and a uniform set of toys. In order to meet design

requirements for simplicity for this new scale, the laboratory setting was abandoned in favor of observing the patient in their real-life settings. Simplified objective definitions of behaviors were agreed upon, and a data sheet was developed that can be easily scored by hand.

Psychometric Data

High degrees of interrater reliability (novice vs. experienced observers) and test-retest reliability were achieved. Validity when compared to the Alpern-Boll Scale was highly significant ($p = <0.001$). Subscales (sensory motor, social relationship to people, affectual responses, sensory responses, language, and overall score) were highly correlated ($p = 0.001$).

Clinical Uses

The Ritvo-Freeman Real Life Rating Scale is particularly useful for measuring changes over time in the symptomatic behaviors of children with developmental disabilities, in particular autistic disorder. It has gained wide spread use in assessing the effects of behavioral and pharmacological treatments.

Reasonable Accommodation

Amiris Dipuglia
Pennsylvania Training and Technical Assistance
Network, Harrisburg, PA, USA

Synonyms

Adjustment; Appropriate adaptation; Modification

Definition

A reasonable accommodation is an adaptation, modification, or change of the educational environment, the presentation of educational material, the method of response, or the educational content. Schools are expected to make the necessary changes that will allow students with disabilities to learn in spite of a fundamental weakness or deficiency. Reasonable accommodations are determined based on individual student needs and should be made based on an evaluation of obstacles or barriers that interfere with the student's access to the school facilities, the classroom, instruction, or student performance. Reasonable accommodations are intended to make it possible for students with disabilities to have an equal opportunity to education. There are several different types of accommodations; some examples include:

- Arranging location and or furniture for accessibility purposes
- Offering alternative ways of completing assignments or responding on assessments (e.g., oral vs. written)
- Curriculum or program modifications
- Test modifications (e.g., reduced number of items on tests)
- Time extensions to complete assignments and assessments
- Assistive technology equipment
- Document conversion (e.g., braille, large print, audiotape)
- Auxiliary aids and services (note takers, lab or library assistants, readers, interpreters)
- Captions for video material

Reasoning on the Autism Spectrum

Mark Brosnan and Chris Ashwin
Centre for Applied Autism Research, Department of Psychology, University of Bath, Bath, UK

Definition

Autism spectrum disorder is associated with relative weaknesses in contexts that require intuition and relative strengths in contexts that require deliberation. Intuition involves rapid, effortless, parallel, nonconscious processing that is independent of working memory and cognitive ability. Deliberation, on the other hand, involves slower, effortful, sequential, conscious processing and is heavily dependent on working memory and related to individual differences in cognitive ability.

Historical Background

“Every fully functioning human adult shares a sense that the ability to think, to reason, is a part of their fundamental identity” (Holyoak and

Morrison 2012:1). Holyoak and Morrison argue that thinking and reasoning are the defining attributes of being human and that incapacity to think or reason has a far greater impact upon us than loss of language or sensory processing capabilities. There is relatively little literature examining thinking and reasoning in autism spectrum disorder (ASD), which is surprising as early reports have noted a capacity to hold forth, like a “little professor,” on their favorite subject or area of expertise, often failing to detect that their listener may have long since become bored of hearing more on the subject (e.g., Gillberg 1991). Thus, ASD has frequently been characterized in terms of relative strengths and weaknesses in different aspects of cognition. For those with ASD, their strengths (including their favorite subjects and areas of expertise) often fall within nonsocial domains and weaknesses within social domains, which may relate to the two diagnostic criteria of restricted, repetitive patterns of behavior, interests, or activities and deficits in social communication and interaction (respectively; APA 2013). These relative strengths and weaknesses in ASD can be understood within the framework of Dual Process Theory, which has been a dominant model within psychology for over 50 years.

Two types of thinking and reasoning are proposed within Dual Process Theory. Type 1 is also termed intuitive reasoning, and is autonomous and typically involves rapid, effortless, parallel, non-conscious processing that is independent of working memory and cognitive ability. Type 2 is also termed deliberative reasoning, and involves slower, effortful, sequential, conscious processing and is heavily dependent on working memory and related to individual differences in general cognitive ability. Intuitive processes are assumed to yield default responses in most situations, unless intervened upon by distinctive higher order deliberative processes. The idea that intuitive processing is the default and generally precedes deliberative processing is known as the ‘default-interventionist position’ (see Evans and Stanovich 2013; Kahneman 2011). Effective social communication and interaction is argued to be typically supported by more automatic, rapid and effortless

intuitive processing which helps to promote prosocial behaviour, such as cooperation (Rand et al. 2012).

Current Knowledge

The Dual Process Theory of Autism proposes that thinking and reasoning in ASD can be characterized as involving relative strengths in the typically slow and conscious deliberative processing, combined with a relative weakness in the typically rapid intuitive processing (Brosnan et al. 2016a, 2017). Luke et al. (2012) used self-report methodology to identify three core features of thinking and reasoning that were particularly problematic for people with ASD: (1) difficulties when talking to others; (2) problems related to changes in routine; and (3) difficulties when thinking or reasoning had to be undertaken quickly (e.g., quickly making a decision). While difficulties talking with others and changes in routine reflect the core diagnostic features of ASD, the difficulty with rapid thinking and reasoning for those with ASD does not currently reflect within the diagnostic criteria. Applying Dual Process Theory to autism (Brosnan et al. 2016a, 2017), difficulties making decisions that involve talking with others and rapid processing would reflect diminished intuitive processing, whereas difficulties making decisions that involve a change of routine would reflect relatively dominant deliberative processing. Consistent with this, behaviorally, people with ASD request more information prior to making a decision upon a probabilistic reasoning task compared to controls, a style of reasoning that has been termed a “circumspect reasoning bias” (Brosnan et al. 2014a). Intuitive processing is argued to be evidenced by “the framing effect” in which logical reasoning is influenced by the context of the reasoning task. De Martino et al. (2008: 10,746) report a decreased susceptibility to the framing effect in people with ASD, who demonstrate an “unusual enhancement in logical consistency.” Together, these research findings show a style of reasoning in ASD characterized by dominant deliberative processing alongside diminished intuitive processing.

One of the most widely used behavioral assessments of intuition and deliberation is the cognitive reflections test (CRT; Frederick 2005). The CRT comprises reasoning questions that have both an intuitive (incorrect) and deliberative (correct) response. An example includes the bat and ball problem: “A bat and ball together cost \$1.10. If the bat costs \$1 more than the ball, how much does the ball cost? . . .” People typically respond to the CRT questions with a majority of intuitive responses (Frederick 2005), which is theorized to reflect output from initial intuitive reasoning processes which have not been overridden by deliberative reasoning mechanisms. The overriding of initial intuitive reasoning by subsequent deliberative reasoning is demonstrated by achieving the correct answer. In the bat and ball problem, most people provide the intuitive response of 10 cents and a small proportion of people provide the deliberative response of 5 cents. There is evidence to suggest that those from the general population who respond with the deliberative response, do so by having overridden the intuitive response (Travers et al. 2016). Consistent with this, experimental manipulations designed to encourage participants to engage in deliberative reasoning (e.g., by taking longer time to respond) reduces intuitive responses (Evans and Curtis-Holmes 2005). Brosnan et al. 2016a, 2017 used the CRT and found that participants with ASD were significantly more likely to provide deliberative responses than the control participants, who instead were more likely to provide intuitive responses. This style of greater deliberative responding in ASD was not related to measures of IQ in those studies, showing enhanced deliberative thinking and reasoning in ASD is not just explained by differences in general ability. Importantly, the Dual Process Theory of Autism proposes a predisposition in ASD towards greater deliberative processing and less intuitive processing. However, while someone with ASD may have a reasoning style predisposed them to engage in more deliberative processing when thinking and reasoning, the output from the excessive deliberation may not necessarily be correct when attempting tasks, such as assessments of IQ. The Dual Process Theory of Autism proposes

a drive towards deliberation during thinking and reasoning, rather than greater deliberative ability per se.

Within the CRT, deliberative responses actually represent correct responses while the intuitive answers are wrong answers. Therefore, a drive towards deliberative reasoning can be seen as a potential advantage for those with ASD in such contexts. Since the intuitive responses are incorrect in the CRT, the extent to which the CRT can be viewed as a measure of intuitive ability has been questioned by Pennycook et al. (2016), who instead suggest it may better be viewed as a measure of intuitive preference and argue that the CRT is a unique predictor of susceptibility to biases. As biases occur through the application of automatic, typically rapid and effortless intuitive processes rather than engaging in further effortful deliberative processing, the CRT can be seen as a particularly potent measure of “miserly” cognitive processing (or “lazy thinking,” Kahneman 2011: 48). From this perspective, ASD is associated with not being cognitively miserly (or lazy thinking), or perhaps with a drive within thinking and reasoning towards being correct or having the correct response (see Brosnan et al. 2016b). Therefore, the bias towards deliberation is best characterized as being unbiased, as it is not influenced by context, at least within the context of the CRT. This has parallels with views of autism characteristics as differences in “style” of processing, rather than a deficit (e.g., Happé 1999). From this perspective, the thinking and reasoning style characteristic of ASD is biased towards deliberative processes, indicating that reasoning is less susceptible to potentially erroneous biases in ASD (Brosnan et al. 2016a, 2017; De Martino et al. 2008).

Despite the benefits of deliberative processing and the susceptibility to bias and error inherent to intuitive processing, intuition can be invaluable and indeed necessary in many instances requiring a quick decision. This is especially true in dynamic social situations in real life. Many social and emotional processes which support prosocial behavior are typically associated with intuitive processing because they involve rapidly changing situations requiring fast judgments and responses

(Evans and Stanovich 2013; Rand et al. 2012). A reasoning bias characterized by reduced intuitive processing may result in social difficulties consistent with those seen in ASD. For example, when recounting a story, someone might perceive quick and subtle cues of boredom in others, and so intuitively alter the story to suit the audience's mood. They might adapt quickly to the situation, either by making it more interesting or by ending it quickly. If someone with ASD (such as the "Little Professor" described above) noticed the same cues while recounting a story, they might not intuitively make such a fast and automatic alteration to the story. In fact, by utilizing deliberative processing while also trying to recount the story, it might actually lead to an even longer and more laborious story, which would exasperate the situation further. In this example, social communication and interaction difficulties in ASD can be related to difficulties with automatically utilizing the rapid and effortless intuitive processing, and instead relying more on the slower and more conscious deliberative processing. Consistent with this, Mendelson et al. (2016) suggest that a slower, inefficient, social information processing speed specifically underlies many social deficits commonly found in ASD, such as the ability to develop and maintain friendships. As Darius (2002) recounts: "There is no such thing as adequate delayed social reactions. One is either quick enough to keep up, or one is weird and socially disabled." Rapidly and automatically extracting emotional information from social environments is argued to be an intuitive process that feeds "downstream" empathy processes and related social-emotional functioning (Kahneman 2011). Thus, the unbiased use of deliberation proposed by the Dual Process Theory of Autism may relate to the social-emotional weaknesses which form part of the diagnostic criteria for ASD. Similarly, intuitive processing can produce a rapid and automatic sense of a "bad feeling" about someone else and lead to behaviors that minimize the risk of being bullied, exploited, or harmed. However, reduced intuitive processing in ASD might not automatically produce these "gut feelings" about others, which may be related to higher levels of bullying reported in ASD (see Maïano et al.

2016). In this situation, deliberative processing is less likely to produce this "bad feeling," resulting in greater vulnerability to harm in ASD.

A relative bias towards deliberative processing within the Dual Process Theory of Autism may also provide an account of the strengths associated with ASD in the literature, including pattern recognition and attention to detail (e.g., Baron-Cohen et al. 2009). Such capabilities are typically highly visual-spatial in nature and have been found to correlate with self-report and behavioral assessments of deliberative processing, such as the CRT (Brosnan et al. 2014b). It seems plausible to speculate that a greater attention to detail and appreciation of patterns within incoming data (e.g., visual-spatial information) would require more conscious processing resources (e.g., working memory) and therefore increase the likelihood of overriding of initial, potentially biased and erroneous, intuitive processing, resulting in a bias towards more deliberative processing. Although not causal, consistent with this, those with heightened attention to detail also have exceptional working memory capacity (i.e., non-autistic child prodigies, Ruthsatz and Urbach 2012). Weak Central Coherence accounts of ASD (e.g., Happé 1999) also embrace greater attention to detail to describe a local processing bias relative to processing the context of the global picture. Evans and Stanovich (2013) identify contextualized processing as a typical correlate of intuitive processing and decontextualized abstract reasoning is typical of deliberative processing, although this is not a defining feature as not all deliberative processing is context-free. The visual-spatial processing of global, gist, or gestalt stimuli has been found to be compromised in ASD (e.g., Brosnan et al. 2004), which may be relevant to typically rapid intuitive, contextualized visual processing. Within the Reverse Hierarchy Theory of visual perception, an initial rapid processing of low spatial frequency information for gist (vision at a glance) is proposed to precede a slower detailed processing of high spatial frequency (vision with scrutiny; see Vanmarcke et al. 2016). ASD may be characterized early on by a bias towards processing high-spatial visual information (Kéïta et al. 2014). Thus, there may be a

series of theoretical models that can be linked to provide an account of ASD characterized as vision with scrutiny leading to greater attention to detail, which in turn requires further processing that leads to a bias favoring deliberative processing. However, there are still outstanding questions. For example, whether Weak Central Coherence is a result of compromised global processing or enhanced local processing (see also Enhanced Perceptual Theory, Plaisted 2001). Consistent with the visual-spatial literature, there are at least two potential explanations for the pattern of a bias towards deliberative relative to intuitive processing in ASD: (1) those with ASD have impaired intuitive mechanisms and consequently deliberative reasoning is dominant; (2) intuitive mechanisms are intact but dominated by deliberative reasoning. It will be interesting to explore in future research if relative weakness in global visual-spatial processing and/or relative strengths in visual spatial local processing align with relative weakness in intuitive processing and/or relative strengths deliberative processing.

The Dual Process Theory of Autism would predict an increased propensity to engage in deliberative processing is situations that typically engage intuitive processing in the general population. For example, emotion recognition is often a rapid and effortless intuitive process in the general population, but people with ASD are reported to utilize more conscious and effortful processing to read the emotional expressions of others (e.g., “corners of mouth turned down + lowered eyebrows = sad”: Rutherford and McIntosh 2007; see also Brosnan et al. 2015). Dual Process Theory would predict that more intuitive tasks, such as emotion recognition, would be independent of working memory and cognitive abilities in a general population. The Dual Process Theory of Autism would predict that people with ASD would utilize deliberative reasoning over intuitive processes, such that emotion recognition capabilities in ASD would relate to working memory or general cognitive abilities (see Harms et al. 2010, for review of the evidence for this). We would predict that those with higher IQs within the ASD population would have greater deliberative capabilities, which may enable the development of

deliberative processing to overcome diminished intuitive processing in some contexts and tasks. However, it will not always be possible for those with ASD to utilize strengths in deliberative processing to overcome or compensate for weaknesses in intuition, such as in the example with the “Little Professor” above.

Future Directions

In terms of potential support or intervention, the Dual Process Theory of Autism would predict that structuring environments so they better support deliberative processing would be most beneficial for those with ASD. For example, physically slowing down incoming stimuli would enhance the performance of those utilizing deliberative reasoning strategies (Tardif et al. 2007). In addition, making content, processes, and communications both sequential in nature (rather than many things happening at once) and explicit (rather than implicit) to better enable conscious processing of relevant information would also enhance the performance of people with ASD by utilizing their deliberative reasoning strategies. Within the general population, the extent to which individuals engage in intuitive or deliberative reasoning has been found to be susceptible to manipulation. For example, being told to “think carefully” or to write down details of how you came to a decision have been found to elicit more deliberative responses, where as being instructed to go with a “gut-feeling” has been found to elicit more intuitive responses (Dijkstra et al. 2012). These are important future considerations, as if reasoning in ASD is characterized by diminished intuitive mechanisms, whether manipulations such as “go with your gut feeling” would affect those with ASD is an open question future research. Pennycook et al. (2016) suggest that “intuitive” individuals may or may not detect the need to think analytically about the problem, but they decide nonetheless to “go with their gut.” Knowing what your “gut is telling you” is a form of interoception. More formerly, interoception is defined as the integration of internal sensations of bodily arousal in the processing of emotional states. It has recently been suggested

that deficits in interoception may relate to many characteristics of autism (Ondobaka et al. 2017). Future research can establish the link between interoception, “gut-feelings,” and intuitive processing.

There are currently few if any measures of intuitive ability (Pennycook et al. 2016). The CRT index of intuitive preference is assessed through providing responses that are actually wrong, for example. Many assessments of IQ are strongly associated with assessments of deliberative ability (see Pennycook et al. 2016). Thus an assessment of intuition that is independent of deliberation would be welcome. Similarly measures that separate out drive and ability for both intuition and deliberation would allow for further exploration of the extent to which ASD is characterized by a drive towards deliberation rather than deliberative reasoning ability per se. Finally, if rapid, effortless, parallel, nonconscious processing (intuition) is not undertaken within social situations in autistic people, it would be fascinating to identify if rapid, effortless, parallel, non-conscious processing was undertaken in nonsocial situations – for example, having an “intuition” about how a mechanical system may be fixed. When thinking about systems, Baron-Cohen defines a “systemizing” as the drive to analyse or construct systems. What defines a system is that it follows rules, and when we systemize, we are trying to identify the rules that govern the system, in order to predict how that system will behave (Baron-Cohen 2003; Baron-Cohen et al. 2009). Within Baron-Cohen’s model, systemizing is distinct from social-emotional processing (termed empathizing). This would suggest that an “intuition” about how a mechanical system may be fixed, or a drive to “intuitively” systemize (e.g., Baron-Cohen 2003: 3), may be distinct from the intuition characterized by typical intuitive processing (see Brosnan et al. 2013, 2014b). Future research can explore the potential relationships between a drive to systemize and a bias towards deliberation. Initial data from both Baron-Cohen and our lab indicates that self-reported systemizing positively correlates with self-reported deliberation but only the latter correlates with actual reasoning performance. Speculatively, Singleton

et al. (2014) have found early evidence that the physiological arousal associated with social stimuli in the general population is associated with nonsocial stimuli of special interest in those with ASD. If such physiological responses relate to “gut feelings” and intuitive processing, the Dual Process Theory of Autism may develop in future to provide a detailed account of the different contexts within which people with and without ASD engage in intuitive and deliberative processing.

In summary, ASD can be characterized by a style of thinking involving greater deliberative over intuitive reasoning, which can be beneficial in some contexts, such as processing information in an unbiased manner. However, this reasoning style is more effortful and time-consuming and therefore not as effective within the fast moving social world. A bias away from intuitive processing and towards deliberative processing, relates to difficulties in social processing in real-time and the Dual Process Theory of Autism may not only account for thinking and reasoning in ASD but also relate to the social communication and interaction diagnostic criteria. The extent to which greater deliberative thinking and less intuitive thinking may relate to restricted and repetitive interests, activities, and behaviors can also be explored in future research.

Recall

► Retrieval of Information

Recency Effect

► Primacy Effects

Recency Effects

Megan Van Ness

Department of Psychology, University of Notre Dame, Notre Dame, IN, USA

Definition

The *recency effect* is a phenomenon of memory in which individuals recall items presented at the end of a list better than items presented in the middle of the list and (sometimes) the beginning of the list. Moreover, when asked to recall events from a list, people have a tendency to start with words at the end of the list. The recency effect is one component of the serial position effect in which individuals tend to remember items from the beginning (primacy effect) or the end of a list better than the middle of the list. Unlike the primacy effect, the recency effect does not decrease

when the number of items on the list increases. Recency effects are strongest for verbally, rather than visually, presented items. The recency effect consistently occurs on immediate free recall tasks but is reduced on delayed free recall tasks when an individual is given a task to complete in the period between learning and recall.

Individuals with autism spectrum disorders (ASD) have different strengths and weaknesses in memory tasks depending on their verbal ability. Individuals with ASD who have higher verbal/intellectual abilities (sometimes called “high functioning”) perform just as well as typically developing individuals on free recall tasks and exhibit the expected primacy and recency effects. Furthermore, individuals with ASD with lower verbal/intellectual abilities are impaired in memory tasks; they do not display primacy effects but remember an overall similar amount of items due to an enhanced recency effect.

Recent Developments in Understanding Friendship of Children and Adolescents with Autism Spectrum Disorders

Neysa Petrina¹, Mark Carter² and Jennifer Stephenson²

¹University of Sydney, Sydney, NSW, Australia

Definition

The conceptual definition of friendship can be summed up as “stable, frequent, and interconnected affective interactions that are manifested by certain classes of behavioural markers (e.g., sharing, play and conversational skills) that facilitate the functions of companionships, intimacy, and closeness” (Bauminger et al. 2008, p. 136).

Historical Background

The impairments in the areas of social interaction and communication, which are core features of autism spectrum disorder (ASD), and problems with emotional and social reciprocity (Fuentes et al. 2012) may result in difficulties in establishing peer relationships appropriate to the child’s developmental level. A growing body of literature has now documented some important differences and similarities in behavioral and affective manifestation of friendships, between typical children and those with ASD. This area of research is rapidly developing, and several recent developments in children and adolescents with ASD will be reviewed.

Current Knowledge

Congruency in Friendship Quality Perception

Friendship by its nature involves social exchanges that are voluntary, reciprocal, and mutual. The dyadic nature of friendship necessitates that the

viewpoints of both dyad members be taken into consideration. The majority of existing studies on friendship have looked at the pattern of friendship of children with ASD as compared to typical children but have not taken the perspectives of the friend into consideration. Two outcome measures have been used to analyze the dyadic nature of friendship, namely, level of dyadic reciprocity and congruency of the friendship.

Dyadic reciprocity is a measure of how each dyad member judges the other participants in terms of their level of friendship (e.g., best friends, friends, non-friend). Dyadic reciprocity has been explored in several studies with both typical children and children with ASD (Chamberlain et al. 2007; Kasari et al. 2011; Rotheram-Fuller et al. 2010). They demonstrated that children and adolescents with ASD had a consistently lower level of reciprocity across nominations of their top three friends and best friends as compared to typically developing matched peers. These results suggest that children with ASD may often perceive friendship relations differently to those they nominate as friends.

Friendship congruency is a comparative measure on how each individual in the dyad views his/her friendship. The analysis of congruency in friendship quality is deemed important since an individual’s perception of his/her friendship quality often impacts on both their own behavior toward their partner and also their evaluations of their friend’s behavior (Furman 1996). It is therefore possible that a difference in perceptions may place a relationship at risk of breakdown. Furthermore, a lack of congruence may also indicate that the perceptions of children with ASD may not accurately reflect the nature of the relationship.

The only study on friendship congruency in children with ASD was done by Petrina et al. (2016). In their study, perceptions of friendship quality of children with ASD were compared to their nominated friends within the same relationships. There were two groups of friendship types. The non-mixed group comprised those where the nominated friend had ASD and mixed group those where the child with ASD nominated a typically developing peer. The Friendship Quality Questionnaire (FQQ; Parker and Asher 1993) was administered to a total of 45 children with ASD

(mean age = 8.5; SD = 0.9) and their nominated friends.

Calculation of the absolute differences in scores between the members of the dyads gave an indication of the magnitude of differences across different dimensions of friendship quality (namely, companionship and recreation, conflict resolution, conflict and betrayal, help and guidance, intimate exchange, and validation and caring) across the dyad partners. In comparison with their nominated friends, children with ASD had substantial differences in perceptions of their friendship quality. Interestingly, the disability status of the dyad partner had no effect on the level of friendship congruency reported. However, when averaged across both groups (mixed and non-mixed dyads), the largest discrepancies were observed in the areas of conflict resolution and intimate exchange. This indicates that the greatest difference in perspectives centered around the concept of how disagreements were resolved and also differences in perspectives on the degree of intimate disclosure of personal information and feelings. This direct approach in quantifying the difference in the perspectives of friendship quality across the friends can give us clearer insight into which area of social skills can be improved for greater positive friendship experience.

Friendship Satisfaction

While extensive research has provided documentation of quantitative differences in the quality of friendships involving children with ASD (Petrina et al. 2014), there has been limited research explicitly examining the degree to which individuals are satisfied with friendships. Given that conceptualization of friendship may be different in children with ASD, it is possible that, while quantitatively different, their relationships may be perceived as satisfying in the sense that they meet individual needs and expectations (Calder et al. 2013; Petrina et al. 2017).

Calder et al. (2013) conducted research with children with ASD aged between 9 and 11 years. These children rated friendship quality as lower than typically developing peers, particularly affective dimensions, consistent with previous findings. In qualitative interviews, however, all but one of the children reported that they were satisfied with their friendships. In addition, Calder

et al. (2013) reported wide variation in the social motivation of children with ASD with regard to friendship formation.

While the level of satisfaction of children with ASD is of interest, the long-term maintenance of friendships is likely to be dependent on the level of satisfaction of both members of a dyad. Petrina et al. (2017) examined this possibility by investigating the friendship satisfaction of 77 children aged 5–10 years with ASD and their nominated friends. Children with ASD were either involved in mixed dyads with a typically developing friend or non-mixed dyads with another child with ASD. Across both types of dyads, friendship satisfaction ratings were relatively high. In addition, there was a relatively high level of agreement regarding satisfaction ratings within friendship dyads.

While existing research has been encouraging with regard to friendship satisfaction, it should be noted that it has been conducted with preadolescent children. It is possible that these findings may not hold for adolescents, where constructs such as intimacy and self-disclosure may be more important (Petrina et al. 2017).

Friendship Expectations

It has been previously noted that while friendships involving children with ASD are often qualitatively different from typical friendships, children with ASD often report that they are satisfied with their relationships. This raises the question of whether individuals with ASD have different expectations of their friendships, and this issue has been investigated, directly or indirectly.

Researchers have examined the issue of expectations indirectly by asking children to define or describe friendship (e.g., Bauminger and Kasari 2000) and by using assessments addressing understanding of friendship characteristics (e.g., Bauminger et al. 2004). While there have been variations, overall, individuals with ASD have tended to focus less on intimacy and affection and more on companionship. For example, O'Hagan and Hebron (2017) reported a small-scale qualitative study of friendship perceptions, involving three adolescents with ASD as well as a parent for each student and teachers. Key findings were that students did not provide a comprehensive definition of friendship, specifically failing to mention intimacy

and focusing on companionship and helping. O'Hagan and Hebron (2017) speculate that individuals with ASD may "place a higher value on specific aspects of friendship such as reciprocal help and support compared with other factors such as intimacy and duration" (p. 320).

An interesting recent example of an indirect approach providing insight into friendship expectations was provided by Bottema-Beutel et al. (2018). They examined differences in perceptions and responses to vignettes depicting friendship transgressions (e.g., revealing a secret or not returning phone calls) in mentally age-matched groups of third to fifth grade children with ASD ($n = 20$) or typical development ($n = 21$). Overall, there were relatively few statistically significant differences across perception of motivations, goals, or response types between the groups and no differences in ratings of the severity of transgressions. To the extent that perceptions and reactions to friendship transgressions reflect underlying expectations of friendships, the results of this study would suggest differences are relatively minor, but this study had limited statistical power and larger scale replication is needed.

Thus, most existing research providing insight into expectations relies on inference from such measures as friendship definitions or descriptions. An exception is the recent study of Bottema-Beutel et al. (2019), where expectations were more explicitly addressed. Bottema-Beutel et al. (2019) directly asked about 12 friendship expectations with the previously described sample. They found that expectations were very similar between groups with the exception that friends should express care, which was higher in the ASD group. A significant and moderate positive correlation was found between overall friendship quality and expectations in children with ASD but not for the typically developing group. Friendship expectation has also been associated with friendship satisfaction (Petrina et al. 2017), so understanding expectations, from both sides of a relationship, may be important in developing strategies to facilitate stable friendships.

Gender Difference(s) in Friendship

To date there has been little research on friendships of females with ASD, and even less

comparing friendships of males and females with ASD (Cook et al. 2018). It seems that generally females who are more intellectually able have better communication and social skills than males (Sturrock et al. 2019). This may translate into more typical friendship patterns for adolescent girls as they spend more time talking to friends, developing reciprocal relationships with one or two more intimate friends (Cook et al. 2018; Foggo and Webster 2017). Indeed, Sedgewick and colleagues believe gender is a larger determinant of friendship characteristics in adolescents with ASD than is the ASD diagnosis itself (Sedgewick et al. 2016, 2018). Although some researchers have found that the friendships of adolescent girls with ASD are similar to those of typically developing girls, they do have more difficulties with social communication and dealing with conflict. They may abandon a friendship, rather than resolving conflict. They may also be more prone to mask their ASD and remain more as observers, withdrawing from conflict (Moyses and Porter 2015). Other researchers have found that adolescent girls with ASD may be more likely to form friendships with boys with ASD, on the basis of shared interests and activities, or with other girls with ASD or other disabilities rather than with typically developing girls (Cook et al. 2018; Cridland et al. 2014).

Boys with ASD, on the other hand, like typically developing adolescent males, tend to focus more on shared activities, have a larger friendship group, with less emotional sharing and less conflict. They may thus be advantaged in developing more typical friendship patterns based on common activities (Cridland et al. 2014; Sedgewick et al. 2016). Some researchers believe males with ASD are different to both girls with ASD and typically developing males, in that they are less motivated to form emotionally close relationships and are more likely to avoid interactions (Sedgewick et al. 2016). Thus, although boys with ASD may fit into social groups, they are less likely to form deeper and intimate friendships (Mendelson et al. 2016).

Friendship Characteristics Across Developmental Stages

As noted above in the section on gender differences, the nature of friendship in people with ASD

changes over time in ways similar to those who are typically developing (O'Hagan and Hebron 2017). For boys with ASD, shared activities remain a focus, and for girls, intimacy and personal closeness become important. A small number of longitudinal studies with young children have found that ASD-linked difficulties with joint attention and symbolic play predicted aspects of friendships in 8–9 year olds. Those with better joint attention skills as preschoolers were more likely to have closer friendships with less conflict (see, e.g., Freeman et al. 2015).

Some studies have provided insights into changes in friendship patterns over time. Through the early and middle school years, where friendship is linked to shared activities, children with ASD may be well accepted even though they rely more on parental support to form and maintain friendships (Daniel and Billingsley 2010). From early adolescence on, many people with ASD will remain at the periphery of their social groups and experience difficulty making and maintaining friendships (O'Hagan and Hebron 2017; Rotheram-Fuller et al. 2010; Finke et al. 2019).

Future Directions

There has been substantial research comparing friendship characteristics between typically developing children and those with ASD. However, limited attention has been given to examining the perspectives from both dyad members. Given the reciprocal nature of friendship, the study of friendship warrants investigation involving both the dyad members' viewpoints. Recent research studies have also provided indication of similar expectations of friendship of children with ASD and typically developing children. Nevertheless, there are very few studies examining either congruence or expectations, so replication should be a high priority. While there may be quantitative differences in friendship characteristics, recent research has provided an indication that many children with ASD may be satisfied with their friendships. Again, very limited research has been conducted and existing studies have been mostly in preadolescents. Thus, further research to determine the robustness of these findings is a

priority. In typically developing children, the characteristics of friendship evolve predictably over time (Gilfford-Smith and Brownell 2003). We currently have very limited longitudinal data on how friendships in children with ASD differ in their development over extended time periods. While research of this type may be challenging and expensive to conduct, it has the potential to offer substantial insight into the nature of friendship in children and adolescents with ASD, including gender differences.

In addition to the specific suggestions offered to this point, there are some more general issues that should be considered by future researchers. The vast majority of extant friendship studies have provided examination of children in middle childhood who have typical intellectual ability. Many children with ASD have intellectual disabilities (Centers for Disease Control and Prevention 2016), and greater inclusion of this group in research would seem appropriate. In addition, given significant changes in friendship characteristics in typically developing children in the teenage years (Bell 2016), further research in adolescents would seem warranted. Finally, most data on friendship characteristics in current research has been gathered through either interview or written questionnaires. Future researchers should consider making greater use of objective data collection methods including direct observation of friendships in natural settings. Such information has the potential to either verify subjective data or indicate where perceptions differ from actual behavior.

Definition

Receptive language is the ability to understand and interpret information that is being conveyed through speech. It also includes an individual's ability to attend/listen to language. Receptive language delay/disorder frequently co-occurs with other developmental delays including autism. Receptive language deficits related to autism may be secondary to cognitive or symbolic deficits, or to the deficits in attention to social cues and stimuli.

Short Description or Definition

Receptive language disorder involves impairment in the ability to understand, or comprehend, language. Deficits may be observed in the

comprehension of oral, written, gestural, and/or symbolic language systems. All levels of language may be affected, including at the word, sentence, and discourse levels. Comprehension of social and nonliteral uses of language may be particularly impaired in individuals with autism spectrum disorders (ASD).

Categorization

The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR; American Psychiatric Association 2000) defines mixed receptive-expressive language disorder according to four primary criteria (a specific category for receptive language disorders is not included in the DSM-IV-TR, presumably because receptive deficits are typically accompanied by expressive language impairments). The first criterion states that scores received on standardized tests of receptive and expressive language are substantially below those obtained on standardized tests of nonverbal intellectual ability (i.e., discrepancy criterion). Second, difficulties with language interfere with academic, occupational, and/or social functioning. Third, criteria are not met for expressive language disorder or a pervasive developmental disorder. Fourth, the language difficulties must be above and beyond those that are typically associated with environmental deprivation or conditions that may be present in the individual, such as mental retardation, speech-motor impairments, or sensory deficits.

Epidemiology

For individuals with ASD, impairments in social communication (including joint attention, social reciprocity, and language and related cognitive skills) are core features of the disorder (American Speech-Language-Hearing Association (ASHA) 2006). Deficits in social communication skills are related to impairments in receptive language ability. These deficits could range from inability to understand individual words to misinterpreting subtle nuances in a

speaker's intent (e.g., sarcasm, humor). Therefore, it seems reasonable to assume that many individuals with ASD have some degree of receptive language impairment. Although the definition of Asperger's disorder includes no clinically significant delay in language, several researchers question whether language is unaffected in this syndrome (cf. ASHA 2006).

Natural History, Prognostic Factors, Outcomes

The prerequisites for comprehending language begin to develop at birth, if not before. For example, at birth, infants prefer the voice of their mothers over other voices, presumably due to in utero exposure. They are also fascinated by facial expressions and respond to them appropriately.

In the first year of life, typically developing children understand a few words in context. By 18 months, children typically have a receptive vocabulary size of about 100–150 words. Subsequently, children's comprehension of syntactic structure develops as they understand utterances of increasing length and use word-order strategies to facilitate comprehension. Between the ages of 4–8 years old, children have receptive vocabularies of 3,000–8,000 words. Upon learning to read, children's receptive vocabularies increase by about 3,000 words per year, and they are able to comprehend oral and written discourse of increasing complexity (e.g., narratives, expository text).

The ultimate goal in comprehension is to understand the speaker's communicative intention, which (usually) is far more than interpreting an utterance literally. Research indicates that young children are able to infer a great deal about the communicative intention of a speaker before they are able to understand the words and sentences. This ability to use social knowledge to interpret a speaker's intentionality is critical for communicative effectiveness. For example, listeners must be able to understand the preparatory and sincerity conditions for speech acts (e.g., understanding a speaker's intention behind the utterance, "Is the Pope Catholic?"). We must also understand scripts for various communicative

situations. For example, when a waiter asks, “What would you like?” we know he is referring to what is on the menu. The ability to inference is also required given that a great deal of information is not explicitly stated in conversations or written texts (e.g., “I was hungry so I went to the restaurant,” infers that a meal was ordered and eaten). Understanding (or at least making educated guesses) about the psychology of other people helps us appropriately interpret the communicative intents of others.

Receptive language impairments may vary in their symptoms and level of severity. Some individuals may not understand even single words, while others only have difficulty comprehending more advanced forms of language, such as expository discourse or academic texts. Toddlers and preschoolers with early receptive language delays tend to have poorer outcomes than children with only expressive language delays. Receptive language ability is lower in children and individuals with intellectual disability, ASD, and various genetic syndromes where cognitive development is affected. In general, IQ is related to language outcomes (e.g., higher IQs are associated with better language skills). Individuals with ASD may have greater deficits with receptive language than expressive language (especially in the early years), and throughout development, they may show higher rates of improvement in their expressive language abilities compared to their receptive skills.

Clinical Expression and Pathophysiology

According to the American Speech-Language-Hearing Association (ASHA 1993), a language disorder is the “impaired comprehension and/or use of a spoken, written and/or other symbol system. The disorder may involve (1) the *form* of language (phonology, morphology, and syntax), (2) the *content* of language (semantics), and/or (3) the *function* of language in communication (pragmatics) in any combination.” In the case of individuals with receptive language disorders, the comprehension (i.e., reception, understanding) of language is impaired. All levels of language may

be affected, including at the word, sentence, and discourse levels. Most individuals with receptive language disorders also have expressive language impairments, with receptive skills superior to expressive abilities. In individuals with autism, however, receptive language may be more impaired than expressive language. For the entire autism spectrum, comprehension of social and nonliteral uses of language may be particularly impaired, given that the meaning of conversations and other discourse (usually involving language) is closely linked to nonverbal cues (e.g., facial expressions), paralinguistic features (e.g., intonation, emphatic stress, prosody), and other aspects of communication that require social awareness for accurate interpretation.

One of the first signs of ASD is a lack of responsiveness to social interactions. For example, infants later diagnosed with ASD were described by their parents as uninterested in human voices or faces. They rarely engaged in social games such as “peekaboo.” All of these behaviors are important precursors to developing receptive language abilities and effective communication skills. Parents of children with ASD report becoming seriously concerned about their children’s development during the toddler years, especially when their children exhibit a lack of responsiveness to words. In the second year of life, the receptive language abilities of children with ASD are depressed relative to their expressive abilities. The gap tends to narrow over time, with receptive and expressive language abilities becoming more similar by ages 3–4 years.

While a great deal of attention has been paid to the expressive language skills in individuals with ASD (e.g., echolalia, idiosyncratic language), less focus has been given to their receptive language and communication abilities. This is unfortunate given that an early lack of response to language is a strong indicator of autism in infants and toddlers. Persistent delays in language comprehension are a key differentiator between children with high-functioning autism and specific language disorders. Although older children with autism may score similarly on standardized tests of receptive and expressive language, they often appear to

be significantly more impaired in receptive language in terms of everyday functioning.

Individuals with ASD often have difficulty comprehending nonliteral uses of language, such as figurative language and indirect speech acts. Figurative language is language that is used in nonliteral ways in order to achieve a special effect or meaning. Similes, metaphors, idioms, proverbs, and slang are examples of figurative language. Upon hearing the expression “It’s raining cats and dogs,” an individual with ASD may think that the speaker means that cats and dogs are literally falling from the sky. Indirect speech acts (i.e., messages where the intended and literal meanings are different) may also be interpreted literally by individuals with ASD. For example, the utterance, “Can you pass the salt, please,” should not be answered with “yes.” Rather, it is an indirect (i.e., polite) way of asking someone to perform an action. The ability to comprehend and produce nonliteral language is an important area of linguistic development in school-age children. Figurative language is commonly used in a variety of communicative contexts, including casual conversation, teacher talk, and written texts. The meaning of figurative language and indirect speech acts may need to be explicitly taught to individuals with ASD. Many researchers believe that difficulties in understanding nonliteral language and social communication are related to deficits in “theory of mind,” or the ability to conceive of other people’s mental states and perspectives.

Some individuals with ASD, particularly those with normal range IQ, may develop grade-level reading skills, although their ability to decode text is superior to their ability to comprehend what they are reading. Often basic reading comprehension is present for topics that require little social knowledge (e.g., science) but is compromised when the text involves social topics such as emotions, character motivations, deception, and other topics that require social awareness and psychological understanding. Higher-functioning individuals with ASD have persistent deficits in comprehending social conversation, especially when sarcasm, humor, slang, and other nonliteral forms of language are involved.

Evaluation and Differential Diagnosis

Language comprehension in young children is assessed through informal observation, parent report/interview (e.g., *Receptive-Expressive Emergent Language Scale-3rd Edition*; Bzoch et al. 2003), or standardized assessments, although very few are available for children under 3 years of age (e.g., *Communication and Symbolic Behavior and Play Scales-DP*, Wetherby and Prizant 2003; *Peabody Picture Vocabulary Test-4th Edition*, Dunn and Dunn 2007; *Preschool Language Scale-5*, Zimmerman et al. 2011).

Language comprehension in young children tends to be highly context dependent. Children make use of comprehension strategies (e.g., “Do what you normally do”) and other contextual clues which can make them appear to understand more language than they actually do (Chapman 1978). For example, a parent gives her child a doll and a brush and says, “Brush the dolly’s hair.” When the child complies, the parent thinks the child understood the linguistic input, whereas the child may have simply done what comes naturally when given a doll and brush. Therefore, it is important to assess language comprehension without providing contextual clues. Sometimes this is done by asking children to perform unusual actions with objects (e.g., “Kiss the brush”). *The Clinical Assessment of Language Comprehension* (Miller and Paul 1995) is a useful resource which provides a variety of informal assessment procedures.

For older children, adolescents, and adults, numerous standardized tests are available for assessing language comprehension (e.g., *Test for Auditory Comprehension of Language-3rd Edition*, Carrow-Woolfolk 1999; *Clinical Evaluation of Language Fundamentals-4th Edition*, Semel et al. 2003). Additional assessment procedures include criterion referenced assessments (e.g., comprehension of passive sentences, ability to make inferences), informal assessment of complex discourse and written text, and informal observations of communicative ability (e.g., classroom and social situations). A few standardized assessments of pragmatic language skills

(i.e., social use of language) are available (e.g., *Comprehensive Assessment of Spoken Language*, Carrow-Woolfolk 1999; *Test of Language Competence*, Wiig and Secord 1989); however, higher-functioning individuals with ASD may perform well within a structured testing situation. For these individuals, observation within naturalistic communicative contexts may be necessary to identify deficits in the comprehension of social language.

Treatment

The receptive (and expressive) language development of young children with language delays is facilitated by a variety of evidence-based approaches, including prelinguistic milieu teaching, focused stimulation, and conversational recasting. In addition, approaches that focus on parent training, such as It Takes Two To Talk (Hanen Program for Parents), have been shown to be effective.

For individuals with ASD, research has demonstrated that a range of approaches are effective for promoting communication abilities and receptive language skills (cf. ASHA 2006). Common approaches range from naturalistic (e.g., Floor Time, Greenspan et al. 1998) to highly structured, behavioral interventions (Lovaas et al. (1989)). According to the National Research Council (2001), educational interventions for individuals with ASD should begin as early as possible, programming should be intensive with repeated and planned teaching opportunities, teacher-student ratios should be low, mechanisms for ongoing assessment and program evaluation should be in place, and family involvement and training is important. In addition, intervention for individuals with ASD should include spontaneous and functional communication, social skills, play skills, peer interactions, generalization of skills to natural contexts, mechanisms for addressing challenging behaviors, and promoting functional academic skills when appropriate.

For individuals who are literate, written language can be an effective means of communication and can be used for compensatory purposes (e.g., using a script or communication checklist

for functioning within various situations). For example, Social Stories (Gray 1993) use a story format using visual materials to improve an individual with ASD's social understanding of various situations. Technology (e.g., texting, social networking) may assist individuals with ASD in social communication without the stress of face-to-face interactions. Comprehension monitoring strategies for older, higher-functioning individuals with ASD (e.g., checklists) may also be effective. For nonverbal individuals with ASD, the use of augmentative and alternative communication (AAC) strategies is common for facilitating comprehension (and expression). AAC approaches include sign language, Picture Exchange Communication System (PECS), communication boards, and voice output devices.

Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

Receptive lexicon

Definition

Receptive vocabulary refers to the collection of words that is understood by an individual. Vocab-

ulary can be learned through spoken or written language, sign language (i.e., gestures), or through symbols. Words are learned by first recognizing patterns in the auditory or visual input and then attaching a corresponding meaning. Vocabulary development is dependent upon environmental, experiential, and individual factors. A child's vocabulary size and knowledge significantly impacts his or her comprehension of both oral and written language.

Research suggests that although overall vocabulary knowledge may be a relative strength in individuals with autism spectrum disorders (ASD), notable deficits may exist. For example, the acquisition of words that refer to mental state or emotional concepts may be especially impaired. Individuals with ASD may have difficulty generalizing the meanings of words to new contexts (e.g., understanding that the word "dog" can refer to many animals, not just the family pet). In addition, individuals with ASD often have difficulty comprehending vocabulary in nonliteral language (e.g., slang, figures of speech, proverbs, metaphors).

Receptive-Expressive Emergent Language Test (REEL-3)

Elizabeth Allen Technical
Test Development, PRO-ED, Inc, Austin, TX,
USA

Synonyms

[REEL-3](#)

Description

The *Receptive-Expressive Emergent Language Test, Third Edition* (REEL-3; Bzoch et al. 2003) is a 66-item, standardized, norm-referenced test designed to help identify infants and toddlers who have language impairments or other disabilities that affect language development. It may be used as an assessment and planning instrument in early childhood intervention programs mandated under Education of the Handicapped Act Amendments of 1986 (P.L. 99-457). The REEL-3 has two core subtests, receptive language and expressive language, as well as a supplementary subtest, inventory of vocabulary words. Results are obtained from a caregiver interview. The test can be individually administered in approximately 20 min.

The REEL-3 is based on a tridimensional model of language acquisition regarding early language development as the intentional interaction content, form, and use of language. This model is further divided into four overlapping chronological phases: prelinguistic reflexive communication, first words and transition to intentional language use, rapid vocabulary development and initial sentence formation, and adultlike preschool register. The third dimension of the model divides language acquisition into receptive and expressive use.

Items in the REEL-3 are divided into reflective language and expressive language subtests. Both subtests are comprised of 66 items that are completed by a parent or caregiver. Reflective

language items measure a child's responses to sounds or language. Expressive language items measure a child's oral language production. Raw scores are tallied for each subtest then converted to standard scores. The receptive language ability score (RLAS) and the expressive language ability score (ELAS) may be combined into a single composite score, the language ability (LAS) score. The LAS can be considered an overall measure of language ability.

Historical Background

The REEL was originally published in 1971 to help identify problems in early language development of infants and toddlers aged birth to 3 years. The REEL was a 132-item checklist of developmental language milestones and corresponding age placement. Items on the REEL were developed from observational research of emergent language in a language laboratory and through early language research. The REEL was edited by the clinical work of multidisciplinary teams.

The REEL required the examiner to interview an informant, usually a parent or caregiver, who was familiar with behaviors consistently used by the child. Checklist items were limited to informant-observable behaviors directly related to auditory-oral language. Items on the REEL were grouped by chronological age. The REEL was comprised of a receptive subtest, based on listening responses, and an expressive subtest, based on vocalization. The subtests could be used independently or with a combined composite score as an indication of early language development. The REEL received positive acceptance as an assessment tool and was primarily used in clinical settings to identify children needing early intervention and to help design early intervention programs.

The revised edition of the REEL was published in 1991, responding to the expanded diagnostic need of practitioners due to the Education of the Handicapped Act Amendments of 1986 (P.L. 99-57), which emphasized special education service for children with disabilities. The REEL-2 was developed to assist in screening infants and

toddlers for early learning problems in clinical diagnosis and in planned intervention goals.

In response to reviews of the test, the REEL-2 reduced clinical language and jargon in the informant interviews, improved scoring and interpretation, and added an interview to help assess a child's language environment.

The REEL-3 improves on the theoretical and statistical base of the previous versions. In contrast to earlier versions of the test, the REEL-3 is based on a contemporary linguistic model for item selection and score interpretation. This model reflects research in the field of infant and toddler communication and language disorders in young children. The test has also included validity, reliability, and normative studies.

Psychometric Data

The REEL-3 was standardized on 1,112 infants and toddlers from 32 US states. The normative sample was stratified on the basis of age, gender, race, ethnic group membership, and geographic location following 2000 US census data.

The reliability of the REEL-3 was estimated using coefficient alphas (content sampling), test-retest (time sampling), and interrater reliability (interrater differences). Coefficient alphas were calculated on the REEL-3's subtests at 23 age intervals using the entire normative sample. Coefficient alphas for the language ability composite range from 0.74 to 0.98. Coefficient alphas for gender and ethnicity range from 0.95 to 0.98.

Test-retest reliability coefficients range from 0.78 to 0.80. Interrater reliability was estimated using the same test-retest sample. In this study, two raters independently scored mother's responses to the REEL-3 items. Kappa coefficients were then calculated using the Cohen (1960) method. The range of kappa coefficients for the expressive language subtest is 0.79–1.00 with a mean of 0.99.

The REEL-3 validity was estimated using content description, criterion-related, and constructed identification methods. Studies were conducted comparing the relationship between the REEL-3 and other tests of receptive and expressive

language. Correlation coefficients between the *Developmental Assessment of Young Children* (DAYC; Voress and Maddox 1998), communication subtest, the *Early Language Milestone Scale-Second Edition* ELM-2; Coplan 1993), *Cognitive Abilities Scale-Second Edition* (Bradley-Johnson and Johnson 2001), and the REEL-3 scores were calculated. The language ability composite scores on the REEL-3 yielded high correlations (0.60) with the above measures. Subtest standard scores of the REEL-3 are significantly intercorrelated (0.73).

Other validity studies, such as relationship to age, relationship to cognitive measures, and performance of various subgroups, were performed. The correlation between chronological age and the REEL-3 language ability composite was 0.90. The REEL-3 correlated moderately (0.49) with the general cognitive quotient (GCQ) of the *Cognitive Abilities Scale-Second Edition* (CAS-2; Bradley-Johnson and Johnson 2001). The performance of selected subgroups of gender, ethnic background, and speech or language impairment on the REEL-2 ranged from 90 to 110. Composite language ability scores for infants and toddlers with speech-language impairments were below average, as expected.

Clinical Uses

The REEL-3 can be used to help identify infants and toddlers who have language disorders. This is useful for identifying infants and toddlers who might benefit from early intervention by speech-language professionals. The REEL-3's norm-referenced scores can be used in reporting and determining eligibility data for special services. Scores may also assist in referral to medical, social, psychological, clinical, or disability services.

Reflective and expressive language subtests of the REEL-3 can be used to determine a significant discrepancy between comprehension process and production in early language acquisition. Significant differences can indicate a need for a specialist in early language development. The REEL-3 can also be used as a measure of a child's language development progress. As a norm-referenced,

standardized, informant based-test, the REEL-3 can be used in further research on early language acquisition.

Structure

An allele is a particular form or “version” of a gene. Typically, this refers to the fact that a

variation in the genetic code is present that distinguishes one set of genetic instructions at the same locus from another. The term “recessive” describes a relationship among alleles of a gene; a trait or phenotype encoded by a recessive allele requires that two copies of that allele are present. In contrast, a trait that is coded for by only one of two alleles is called a dominant trait. An individual heterozygous (one copy each of different alleles) for the dominant and the recessive allele will appear identical to a person carrying two copies of the dominant alleles. The relationship of dominant and recessive alleles was first worked out experimentally by Gregor Mendel using traits in garden peas, such as color and surface texture; the theory of Mendelian inheritance has its origins in these experiments.

Function

One example of a Mendelian trait displaying a dominant-recessive allele relationship in humans would be the disease phenylketonuria: heterozygotes display no symptoms, one functional copy of the protein encoded by the *PKU* gene is sufficient for complete health. The same is true of the disease cystic fibrosis; one functional copy of the protein cystic fibrosis transmembrane conductance regulator, encoded by *CFTR*, is sufficient. However, two copies of the mutant allele would result in disease, making this a recessive disorder. ABO blood types, determined by identifiers on the outside of red blood cells, are another example; in this case, there are three alleles rather than two; while A and B are both dominant to O, they are codominant with each other, so that there are four blood type phenotypes: A (encoded by AA or AO), B (BB or BO), AB (encoded by AB), and O (only encoded by OO) (Griffiths et al. 2000; Miko 2008; OMIM).

Pathophysiology

Recessive alleles are of interest in autism, despite the consensus that autism is generally a

multifactorial disorder and not a single-gene Mendelian condition. Highly deleterious mutations, though not necessarily sufficient alone, may nonetheless account for a large proportion of the risk in individual cases, and thus homozygous mutations in patients with autism are of great interest. A homozygous deletion at *CNTNAP2* was implicated in several Old Order Amish families presenting with cortical dysplasia-focal epilepsy syndrome and autistic features (Strauss et al. 2006). Homozygosity mapping, a technique which specifically seeks out consanguineous families to look for regions that are identical in both copies in the offspring, due to each parent possessing at least one copy through shared ancestry, can be used to associate these homozygous regions with the phenotype of interest. A notable study applying this method to consanguineous families with children with autism demonstrated that this method can reveal rare inherited deletions that are likely to be causative, implicating several genes for which there was already evidence in autism (Morrow et al. 2008). Thus, despite autism’s status as a complex genetic disorder, methodology based on simple Mendelian principles can provide a way to gain insight into the genes involved.

Reciprocal Communication/ Interaction

Brynn Thomas

The Neurodevelopmental Disabilities Laboratory,
Laboratory for Understanding Neurodevelopment
(FUN Lab), Northwestern, and the University of
Notre Dame, Chicago, IL, USA

Definition

Reciprocal communication/interaction is a type of communication in which children use verbal and nonverbal behaviors to engage in mutual, interactive dialogue. Characteristics include (but are not limited to) asking one's conversational partner a question, adding additional information to a statement they make, and/or guiding a conversation to elicit additional remarks from the conversant.

Impaired or absent reciprocity in communication is a diagnostic characteristic of Autism Spectrum Disorder.

Recognition Memory

Laudan B. Jahromi

School of Social and Family Dynamics, Arizona
State University, Tempe, AZ, USA

Definition

Recognition memory involves the capacity to remember familiar stimuli when comparing a novel stimulus with one that is already stored in the memory. The seminal work on visual recognition memory conducted by Fantz (1956) and Fagan (1970) revealed that recognition memory develops in early infancy. When presented with a pair of stimuli (one novel and one familiar), infants look longer at the novel stimulus, encoding new information, and comparing this information to their stored mental representation of the familiar stimulus (Rose et al. 2004). Thus, by showing differential responses to novel and familiar stimuli, infants demonstrate their recognition of familiar stimuli. Factors that may influence one's recognition memory include the physical features of a stimulus, the number of stimuli being held in one's memory, and the amount of time that elapses between familiarization with a stimulus and recognition testing (Rose et al. 2004). Although the findings concerning recognition memory in children with autism have been somewhat mixed (e.g., Boucher 1981; Minshew and Goldstein 1993), there appears to be growing evidence of intact recognition memory among children with autism (Bennetto et al. 1996).

Recovery in Autism

Eva Troyb¹ and Deborah Fein²

¹Neuropsychology, EASTCONN Regional Education Service Center, Columbia, CT, USA

²Department of Psychological Sciences, University of Connecticut, Storrs, CT, USA

Definition

While autism spectrum disorders (ASDs) are generally considered to be lifelong conditions, multiple studies have indicated that a small percentage of individuals who are diagnosed with an ASD in childhood experience a reduction in autism symptomatology to such a degree that they no longer meet diagnostic criteria for any ASD as they get older. The term “recovery” in this context

suggests a complete return to normal functioning; however, the limited available research examining this population suggests that some mild residual deficits are evident in some individuals in this group (Fein et al. 2013). For this and other reasons, the term “recovery” may not be the best way to describe this outcome in ASD (Helt et al. 2008; Sallows and Graupner 2005). Instead, the term “optimal outcome” has been proposed to describe individuals with a history of ASD diagnoses who no longer meet diagnostic criteria for ASD and who demonstrate average academic and adaptive functioning and receive minimal special education supports specific to autism symptoms.

Historical Background

Lovaas first formally used the term “recovery” in 1987, when reporting the results of a study that investigated an early, intensive, behavioral intervention program for ASDs. Lovaas reported that 47 % of his sample exhibited average cognitive functioning after receiving the intervention. Lovaas’ initial report of recovery has been supported by a number of more recent studies that explored the effect of early intensive behavioral treatment for ASDs. These studies reported that a small number of participants responded particularly well to treatment and performed in the average range on some outcome measures by the conclusion of the study (e.g., Cohen et al. 2007; Sallows and Graupner 2005; Zacher et al. 2007). The percentage of children who achieved this positive outcome varied considerably across studies, as did the measures used to assess outcomes.

Numerous longitudinal studies that followed children diagnosed with ASDs also reported that a small percentage of participants with ASDs within their cohort no longer met diagnostic criteria for ASD by the conclusion of the study (Sigman and Ruskin 1999; Stevens et al. 2000; Szatmari et al. 1989; Venter et al. 1992). In Szatmari and colleagues’ (1989) follow-up study of adults with ASD, 25 % of the sample no longer met diagnostic criteria for ASDs when reassessed between 11 and 27 years after initially being diagnosed with an ASD. Venter and colleagues (1992)

followed high-functioning children, adolescents, and young adults with autism over 8 years and reported that 22 % of the sample was included in regular education classrooms with limited or no supports. Sigman and Ruskin (1999) reported that 10 % of their sample lost their ASD diagnosis approximately 9 years after receiving the diagnosis. Similarly, Stevens and colleagues (2000) followed a group of preschool children with an ASD diagnosis for 8 years and found that 25 % of their sample exhibited few symptoms of autism and performed in the average range on measures of verbal and nonverbal reasoning.

Several important criticisms of the phenomenon of recovery from ASD have been voiced and have emphasized the need for a better definition of this concept. First, Piven et al. (1996) documented positive outcomes among individuals previously diagnosed with ASD and suggested that these individuals continue to present with subthreshold symptoms of ASDs. Specifically, Piven and colleagues (1996) reported that communication and socialization symptoms of ASD generally improve by adolescence and adulthood among high-functioning individuals with ASD. However, even among the 13 % of their sample who no longer met diagnostic criteria for ASD in adolescence and adulthood, all continued to present with subthreshold symptoms of ASD that caused substantial impairment in functioning. Seltzer et al. (2004) also argued that because the definition of recovery varied across the studies described above, it remained possible that these cases of recovery simply captured the expected improvement in ASD symptomatology as individuals aged. Additionally, because standardized diagnostic measures were not used regularly to ensure the accuracy of the early diagnosis in many of the studies mentioned above, it remained possible that cases of recovery were actually individuals who were inaccurately diagnosed with ASD when they were younger. Furthermore, many of the studies described above used average IQ scores and placement in regular education classrooms as indicators of recovery. However, high-functioning individuals with ASD would meet these criteria and still retain their ASD diagnosis. To address these criticisms, Helt and

colleagues (2008) reviewed previously published reports of individuals who eventually lost their ASD diagnosis and proposed a rigorous definition for this phenomenon to be used by future studies. The proposed definition described individuals who achieved “optimal outcomes (OOs)” and included having a diagnosis of ASD in early childhood made by an ASD specialist, but no longer meeting diagnostic criteria for any ASD and exhibiting average intellectual, academic, and adaptive functioning, as well as minimal special education support specific to ASD.

Current Knowledge

To understand this population further, several studies have focused on individuals who achieved OOs using a rigorous definition similar to that described by Helt et al. (2008). A study by Fein et al. (2005) described several children diagnosed with pervasive developmental disorder, not otherwise specified in early childhood, who lost their ASD diagnoses by middle childhood, instead meeting diagnostic criteria for attention deficit hyperactivity disorder (ADHD) at reevaluation. While these children no longer met diagnostic criteria for ASD, some of them continued to exhibit perseverative interests and occasional repetitive motor movements, as well as mild social difficulties. The authors suggested that attention difficulties may be a core feature of ASD that is more difficult to address with early behavioral intervention.

In a series of studies, Kelley et al. (2006) and Kelley et al. (2010) sought to uncover the presence of residual deficits among a group of children who were diagnosed with ASDs as toddlers, and at the time of the study exhibited average IQ scores, were mainstreamed into age-appropriate classrooms, functioned at age-appropriate levels according to the report of the children’s parents and teachers, and no longer met diagnostic criteria for any ASD. The first study evaluated the language abilities of 14 such children between the ages of 5 and 9 years and found residual difficulties on measures of pragmatic and semantic language, particularly in understanding the second-

order theory of mind, using mental state verbs, producing a narrative, and using inductive reasoning about animate objects (Kelley et al. 2006). In the second study, Kelley and colleagues (2010) described the functioning of an older OO group that ranged in age from 8 to 13 years. The OO group consisted of 11 children who were included in the first study along with two additional participants. The study employed two comparison groups: typically developing peers and high-functioning peers with a current ASD diagnosis. The three groups were compared on measures of cognitive, adaptive, social, and communicative functioning, ASD symptom severity, and expressive and receptive language. The results showed that the OO group exhibited more difficulties with attention than typically developing peers, but otherwise did not differ on any other measure included in the study, including pragmatic language ability.

Recently, a large retrospective study was conducted at the University of Connecticut that explored the functioning and residual weaknesses of a group of individuals who achieved OOs and documented the range of treatments they received (Fein et al. 2013). The study included 34 individuals who were diagnosed with ASD by a specialist in ASD before the age of 5 years. At the time of the study, participant in the OO group did not meet diagnostic criteria for any ASD by clinical judgment (based on DSM-IV criteria and ADOS), presented with average intellectual and adaptive functioning, and were included in a regular education classroom without one-on-one assistance and no special education services to address ASD-related deficits. Performance across measures was compared to 44 high-functioning individuals with a current ASD diagnosis (HFA group) and 34 typically developing peers (TD group). Groups were matched on age, gender, and nonverbal IQ, but differed significantly on verbal IQ, with the OO and TD groups scoring seven points higher than the HFA group. Parent reports of early development suggested the OO group exhibited milder symptoms of ASD than the HFA group within the social domain, but displayed equally severe difficulties in the communication domain (Fein et al. 2013). At the time

of the study, individuals in the OO group were functioning in the normal range on all measures of communication and social functioning, and, as expected, scored better than individuals in the HFA group in both domains. A comparison of specific behaviors within the social and communication domains across the OO and TD groups revealed that participants in the OO group were significantly more likely to ask for information and showed a trend to offer more information. A proportion of the OO group also displayed a subtle residual weakness in the level of insight into social relationships, and a very small proportion of OO participants still showed suboptimal eye contact (Orinstein et al. 2015a).

With respect to repetitive behaviors, parents of individuals in the HFA and OO groups reported similar levels of restricted and repetitive behaviors early in development, with the exception of milder levels of oversensitivity to noise and insistence on sameness in the OO group. While these behaviors were present in childhood, the OO group's restricted and repetitive behaviors appeared to resolve along with social and communication deficits and had disappeared almost entirely by the time of participation in this study. At the time of the study, restricted and repetitive behaviors were still present in the HFA group (Troyb et al. 2014b).

The cognitive functioning of the OO group was explored across a number of domains. Within the language domain, the OO group scored in the average range or above on all measures of expressive and receptive language and showed few differences from the TD group. The HFA group also performed within the average range, but scored significantly lower than the other groups on formulating sentences and a measure of overall language skills, even when verbal IQ was controlled for (Tyson et al. 2014). Narratives of a subsample of each group were also evaluated (Suh et al. 2014). Participants in the OO group displayed a subtle use of idiosyncratic language and speech disfluency that was not observed in the TD group. Participants in HFA group produced narratives with fewer central story elements and more ambiguous pronominal referents, idiosyncratic language, and
